$$V_{M1}=\frac{V_M}{2}\left[1+\frac{kZ}{Z_C+Z}\right] \qquad (25)$$

and

$$V_{M2}=\frac{V_M}{2}\left[1-\frac{kZ}{Z_C+Z}\right] \qquad (26)$$

Equation 27 becomes

$$T_0=T_B\frac{kZ}{Z_C+Z} \qquad (28)$$

When

$$Z_c=0$$

$$T_0=kT_B \qquad (28a)$$

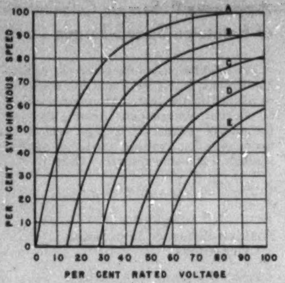

Figure 8. Speed in per cent of synchronous versus control-winding voltage in per cent rated for servomotor operating with $Z_c=0$

Curve "A" is for zero developed torque. Curve "B" is for developed torque of two synchronous watts; "C," $T=4$; "D," $T=6$; "E," $T=8$

Figures 8 and 9 show that the assumption of linearity of speed with control voltage is valid approximately only over limited ranges especially at higher torque loads.

Single-Phase Performance. The curve marked "A" in Figure 3 is a type of single-phase performance in which the voltage across the control winding is held at zero making $V_{M1}=V_{M2}=V_M/2$ at all values of speed. This is not truly single-phase performance as equations 23 and 24 show that the positive- and negative-sequence voltages vary with the impedances of these sequences and consequently the voltages vary with speed. The curve "A" of Figure 3 shows that the motor under discussion can not run with zero control-winding voltage, that is, with the winding short circuited.

This feature can be explained as follows. Since V_{M1} and V_{M2} always have the value $V_M/2$ the torque becomes

$$T=1/4(T_{B1}-T_{B2}) \tag{29}$$

For the motor under discussion, the balanced-voltage speed-torque curve crosses the zero-speed axis with negative slope and T_{B2} is always larger than T_{B1} for corresponding values of speed. Equation 29 then shows what the torque will be opposite to the rotation at all times. In the general-purpose 2-phase motor this curve would cross the zero axis with positive slope and such a machine would develop torque with one phase short circuited. Servomotors, however, must have a speed-torque characteristic crossing the zero axis with negative slope or they will be unstable (See the section on Application to Transient Analysis of Control Systems) in closed-cycle control systems unless there is sufficient load friction or derivative feedback is provided.

True single-phase operation (control winding open) can be explained in somewhat the same way except that the positive-and negative-sequence voltages do not remain constant. Figure 10 shows the relationships between V_1, V_2, T_{B1}, T_{B2}, (defined previously) T_1 and T_2 (positive- and negative-sequence torque for single-phase operation) and T the net torque. It can be seen that the net torque is always negative because of the shape of the balanced-torque curves and because there is not a large variation in the voltages V_1 and V_2. If V_1 had been larger and V_2 smaller at the higher speeds it is possible that this motor could have developed positive net torque single phase. It will be of interest to investigate the factors influencing the variation of the sequence voltages with speed.

Equations 23 and 24 are satisfied by the equivalent circuit of the single-phase induction motor shown in Figure 11.

Reference to this figure will show that the two impedances Z_1 and Z_2 will tend to remain equal if either the stator impedance is high or the impedance of the exciting circuit is low (conductance G and susceptance B large) in comparison with the rotor impedance. The stator and the blocked-rotor value of rotor impedance will normally be of the same order of magnitude. The exciting impedance is low in comparison with the usual induction motor because of the large air gap in the type motor being considered. Therefore Z_1 and Z_2 tend to remain nearly equal, and the voltages V_1 and V_2 tend to remain nearly equal. This coupled with a speed-torque curve which crosses the zero axis with negative slope prevents the motor from developing a running torque regardless of the speed at which the rotor may be caused to rotate. This facet of the discussion emphasizes the beauty of the two-revolving field theory of the single-phase induction motor.

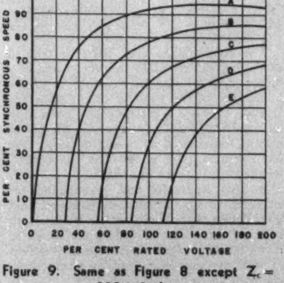

Figure 9. Same as Figure 8 except $Z_c=200+j0$ ohms

Application to Transient Analysis of Control Systems

The important electrical quantities in the transient performance of a servomotor in a control system are its internal damping and its torque-to-control voltage ratio.

It can be shown that the internal damping is equal to the negative reciprocal of the slope of the speed-torque curve.[22]

For a d-c motor with constant flux and neglecting stray load loss, core loss, friction, and windage

$$T=k_tI_a$$

$$I_a=\frac{V_t-k_vN}{R_a}$$

$$N=\frac{V_t}{k_v}-\frac{TR_a}{k_tk_v}$$

$$\frac{dN}{dT}=\frac{-R_a}{k_tk_v}$$

where

k_t = inch-ounces torque per ampere of armature current
I_a = armature current
N = speed in rpm
k_v = generated volts per rpm
V_t = terminal voltage
R_a = armature circuit resistance

The foregoing relations show that the speed-torque curves of a d-c motor are a family of straight lines each having a slope of $-R_a/k_tk_v$ and intercepts on the speed axis of V_t/k_v. Such characteristics permit the description of the transient performance of a motor in either open- or closed-cycle operation by linear differential equations. Although the torque-versus-control voltage curves are fairly straight lines in the case of the 2-phase motor, the damping factor is far from linear as shown by the curves of Figures 12, 13, 14, and 15. These curves show the variation in damping with voltage at several values of speed, also the variation in damping with variation in speed for several values of voltage. They were calculated by taking the instantaneous slopes expressed in terms of ounce-inches per revolutions per minute of the speed-torque curves under the stated conditions.

Curves are shown for both types of operation discussed previously, that is, $Z_C=0$ and $Z_C=200$ ohms resistance. Because of the nonlinearity of the damping and torque curves, control systems employing 2-phase servomotors cannot be described accurately by linear differential equations. It is beyond the scope of this

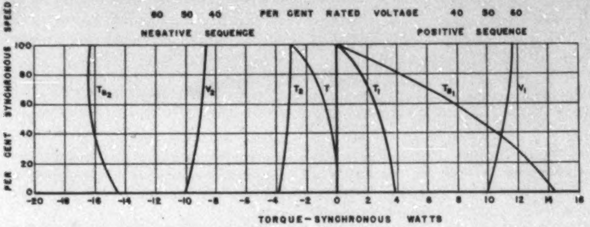

Figure 10. Curves used to explain single-phase performance of servomotors. Positive- and negative-sequence voltage in per cent rated versus speed in per cent synchronous. Torque in synchronous watts versus speed in per cent synchronous

Curve T_{B1} shows torque for operation on balanced 2-phase voltage applied to produce field rotation in direction of shaft rotation

Curve T_{B2} shows torque for operation on balanced 2-phase voltage applied to produce field rotation opposite to shaft rotation

V_1 and V_2 are curves of positive- and negative-sequence components of motor voltage respectively

T_1 and T_2 are curves of torque produced by the voltages V_1 and V_2 respectively

T is net torque T_1-T_2

paper to go any farther than to suggest that when the problem of analyzing the transient performance is met, the speed-torque curves be examined for the extreme of operation which will give minimum damping and again for that which will give maximum. Two solutions each using one extreme value of damping should bracket the actual performance provided the torque curves do not depart too greatly from linearity.

Conclusion

It is shown that the torque of the typical 2-phase servomotor discussed is approximately proportional to the control winding voltage over a normal speed range and that the torque at zero speed is directly proportional to control winding voltage for any servomotor of this type. The speed at constant torque is roughly proportional to voltage at only very limited ranges of low speed as contrasted with the d-c motor where speed at constant torque varies directly with voltage over a wide range in speed.

The damping factor is seen to be a function of speed and voltage and is far from being a constant value as in the d-c case.

Whether or not the motor will operate as a single-phase motor depends largely upon the exciting impedance as compared with rotor impedance and the slope of the balanced-voltage speed-torque curve near zero speed. The criteria are, that if the exciting impedance is low as compared with conventional values, and the balanced-voltage speed-torque curve crosses the zero speed axis with negative slope, the motor will not run single-phase.

Appendix I. Extension to Unbalanced Windings

It is assumed that the windings of the motor are such that sinusoidal magnetomotive-force space waves are produced by current in the windings. Let k_{bM} and k_{bC} be the breadth factors of the main and control windings respectively; k_{pM} and k_{pC} be the pitch factors of the main and control windings respectively; and N_M and N_C the number of turns in the main and control windings respectively.

Then $I_M k_{bC} k_{pM} N_M$ and $I_C k_{bC} k_{pC} N_C$ are the respective ampere turns in the main and control windings.

Assuming uniform permeance in the magnetic circuit, the flux waves produced by the two windings will be equal when

$$\frac{I_M}{I_C}=\frac{k_{bC}k_{pC}N_C}{k_{bM}k_{pM}N_M}=c \tag{30}$$

If $V_C^2=c^2V_M^2$, the same flux waves will be produced if an ideal transformer of turns ratio $c:1$ is placed across winding C and equal voltages applied to both windings. In this case $V_C=cV_M$; $I_C=I_M/c$ which satisfies equation 30. Normally, taking c as the ratio of the rated voltages of the windings should be sufficiently accurate.

The combination may then be treated as having the terminal characteristics of a motor having balanced windings.[23] If the impedance of the winding differs from the relation $Z_C=c^2Z_M$ the methods previously outlined may be used. That is, the motor may be considered as operating as in case one, with voltage applied to the control winding through an impedance.

In this Appendix and throughout the entire discussion it must be assumed that any circuit unbalance, either external or internal, must be confined to the stator as it can be shown that when unbalance occurs in both, the simple analysis by symmetrical components cannot be made.[24,25]

Appendix II. Sample Calculations of Points on Speed-Torque Curve

The calculations are based on the equivalent circuit of Figure 4 and the equations developed in the text. Assume a speed of 60 per cent synchronous. Assume also that the control voltage, E_C, is 50 per cent of the main winding voltage and is applied through a 200-ohm resistor. Then

$E_C=0.5V_M \qquad k=0.5$
$Z_C=200$

Positive-Sequence Impedance Calculations

Positive-sequence slip, $S_1=0.40$.

Positive-sequence equivalent rotor resistance, $R_R/S_1=100/0.4=250$ ohms. Assume that there is one ampere current in the equivalent rotor, then the voltage across the equivalent rotor and the exciting susceptance is $250+j0$. The exciting current is $250\times(-j0.01)=-j2.5$, and the total stator current is $1-j2.5$. The IZ drop through the stator is $(1-j2.5)\ (50+j120)=350-j5$ volts. The total voltage required to cause $1-j2.5$ amperes current in equivalent rotor is

$$350-j5+250=600-j5 \text{ volts}$$

$$Z_1=(600-j5)/(1-j2.5)=$$
$$600\underline{/-0.5}/2.69\underline{/-68.2^\circ}=223\underline{/67.7^\circ}$$

Negative-Sequence Impedance Calculations

Negative-sequence slip, $S_2=2-S_1=2-0.4=1.6$. Negative-sequence equivalent rotor resistance, $R_R/S_2=100/1.6=62.5$ ohms. Assume one ampere in the equivalent rotor, then the voltage across the exciting susceptance is $62.5+j0$; the exciting current is $62.5(-j0.01)=-j0.625$. The total stator current is $1-j0.625$. The drop through the stator is $(1-j0.625)\ (50+j120)=125+j88.75$.

$$Z_2=(187.5+j88.75)/(1-j0.625)=$$
$$207.5\underline{/25.3^\circ}/1.18\underline{/-32}=175.5\underline{/57.3^\circ}$$

Positive- and Negative-Sequence Voltage Calculations

$$V_{M1}=\frac{V_M(1+k+Z_C/Z_2}{2+Z_C/Z_1+Z_C/Z_2} \tag{18}$$

$V_M=75$ volts rated

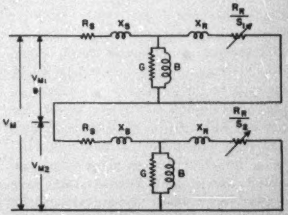

Figure 11. Equivalent circuit of single-phase induction motor

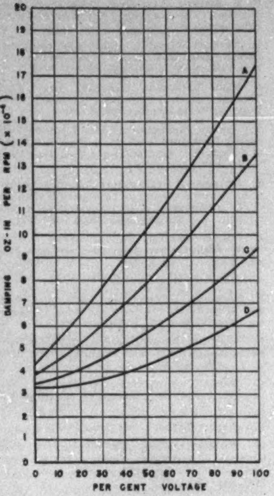

Figure 12. Internal damping factor in ounce-inches per revolutions per minute versus control-winding voltage in per cent rated for $Z_c=0$

Curve "A" is for a speed 60 per cent of synchronous; "B" for 40 per cent; "C" for 20 per cent; "D" for zero speed

$$V_{M1}=\frac{75(1+0.5+200/175.5\underline{/57.3^\circ}}{2+200/223\underline{/67.7^\circ}+200/175.5\underline{/57.3^\circ}}$$

$$=\frac{75(1.5+0.615-j0.96)}{2+0.34-j0.829+0.615-j0.96}$$

$$=\frac{75\times 2.32\underline{/-24.4^\circ}}{3.45\underline{/-31.2^\circ}}=50.4\underline{/6.8^\circ}\text{ volts}$$

$$V_{M2}=\frac{V_M(1-k+Z_C/Z_1)}{2+Z_C/Z_1+Z_C/Z_2} \qquad (19)$$

$$V_{M2}=\frac{75(1-0.5+200/223\underline{/67.7^\circ})}{2+200/223\underline{/67.7^\circ}+200/175.5\underline{/57.3^\circ}}$$

$$=\frac{75(0.5+0.34-j0.829)}{3.45\underline{/-31.2^\circ}}$$

$$=\frac{75\times 1.18\underline{/-46.0^\circ}}{3.45\underline{/-31.2^\circ}}=25.6\underline{/-15.4^\circ}\text{ volts}$$

Torque Calculations

The torque in the direction of motor rotation for balanced-voltage operation at 75 volts is found by standard methods to be 3.9 synchronous watts per phase at a slip of 0.4 or at 0.6 synchronous speed. The torque for reversed motor rotation at 0.6 synchronous speed (backwards) is also found by standard methods to be 8.2 synchronous watts per phase.

Calculating the net torque

$$T=\left(\frac{|V_{M1}|}{V_M|}\right)^2 T_{B1}-\left(\frac{|V_{M2}|}{V_M|}\right)^2 T_{B2}\text{ synchronous}$$

watts per phase, equation (20)

$$T=2\left[\left(\frac{50.4}{75}\right)^2 3.9-\left(\frac{25.6}{75}\right)^2 8.2\right]=$$

1.6 synchronous watts total

Calculations for Control Voltage Directly Applied

$Z_c=0$

Assume $k=0.6$, positive-sequence slip $=0.40$

$$V_{M1}=\frac{V_M}{2}(1+k) \qquad (21)$$

$$V_{M1}=\frac{75}{2}(1+0.6)=60\text{ volts}$$

$$V_{M2}=\frac{V_M}{2}(1-k) \qquad (22)$$

$$V_{M2}=\frac{75}{2}(1-0.6)=15\text{ volts}$$

Torque for balanced operation from above example $=3.9$ and 8.2 synchronous watts per phase for forward and backward rotation respectively.

$$T=2\left[\left(\frac{60}{75}\right)^2 3.9-\left(\frac{15}{75}\right)^2 8.2\right]$$

$=4.2$ synchronous watts total

Appendix III. Discussion of Correspondence between Experimental Data and Theoretical Performance

The equivalent circuit parameters of the motor used as an example in this paper were calculated from open-circuit and short-circuit tests and then modified so as to bring the calculated performance into reasonably good agreement with observed performance. Such procedure was necessary because of the normal difficulty involved in properly separating the rotor and stator reactances by means of blocked-rotor and no-load tests of squirrel-cage induction motors, a difficulty which is magnified in the present case because of the relatively large amount of exciting current.

However, the calculations are straightforward and if the parameters could be determined accurately for each value of positive- and negative-sequence slip, the results would be quite accurate. This is emphasized by the fact that when the experimental speed-versus-torque curve for balanced voltage was available, one of the writer's colleagues was able to predict the curves for various values of directly-applied control voltage with a high degree of accuracy.

When making performance calculations, it is desirable to assume that the leakage inductances and resistances remain constant in order to simplify the calculating procedure. This procedure was followed in constructing the several curves shown in the text material of this paper. There is perhaps more reason to assume that the stator leakage reactance and the exciting admittance remain constant in a "drag cup" motor than in a conventional motor because the large air gap is conducive to more constant saturation conditions.

The conditions in the rotor however are more adverse and it may be expected that the current distribution, and therefore the leakage inductance and the resistance, will change considerably with frequency or slip.

This should not cause great difficulty for the application engineer if the motor manufacturer would furnish the following experimental data:

1. Speed-versus-torque curve for balanced voltages for speed values ranging from 100 per cent positive rotation (slip = 0) to 100 per cent negative rotation (slip = 2).
2. Vector impedance values (as viewed from the terminals) for the same range in speed or slip.

The positive- and negative-sequence voltages could then be calculated by means of one of the following pairs of equations 18, 19; 21, 22; 23, 24; or 25, 26. Torque could be calculated by means of equation 27. Presumably quite accurate values of performance for a variety of operating conditions could be obtained. The accuracy of this method has been checked for the case where $Z_c=0$ as mentioned previously.

These methods, however, do not benefit the motor designer in the same degree. His problem concerns the finding of the various reactances and resistances which make up the terminal impedances. The determination of these values for varying frequency would make worthy subjects for future studies. Following is a description of a method which the writer hopes to use for

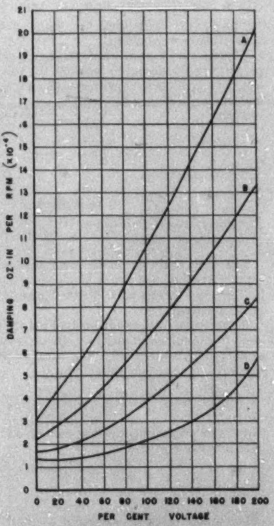

Figure 13. Same as Figure 12 except $Z_c=200+j0$

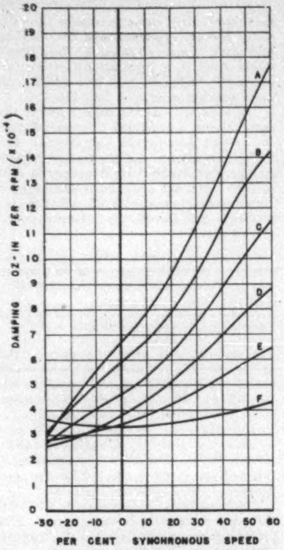

Figure 14. Internal damping factor versus speed for $Z_c=0$

Curve "A" is for control voltage corresponding to $k=1.0$; "B," $k=0.8$; "C," $k=0.6$; "D," $k=0.4$; "E," $k=0.2$; "F," $k=0$

experimentally separating the stator and rotor leakage reactances.

Assume that a search coil can be placed properly in the airgap to measure the voltage corresponding to that across the exciting admittance in Figure 4.

Then

$$V-I_sZ_s=E$$

where

V = terminal voltage
I_s = stator current
Z_s = stator leakage impedance
E = search coil voltage

This test could be made with blocked rotor. Another test could be made at no load or some chosen value of rotor speed in order to change I_s.

If the voltage, V, is adjusted so that the same E is obtained in each case (in order to avoid having to determine the turns ratio of stator coil to search coil), we have

$$V'-I_s'Z_s=E=V''-I_s''Z_s$$

where the primes signify first and second tests respectively, and

$$\frac{V'-V''}{I_s'-I_s''}=Z_s$$

The stator leakage impedance as calculated should remain fairly constant for reasons mentioned previously. The rotor impedances could then be calculated from measured terminal impedances for various slips.

Appendix IV. Nomenclature

V_M = terminal voltage of main winding
V_C = terminal voltage of control winding
V_{M1} = positive-sequence component of V_M
V_{M2} = negative-sequence component of V_M
V_{C1} = positive-sequence component of V_C
V_{C2} = negative-sequence component of V_C
V = terminal voltage for balanced polyphase
E_C = control voltage applied to motor winding in series with impedance external to winding
E = voltage induced in search coil by air-gap flux
k = ratio $|E_C|/|V_M|$
V_t = terminal voltage of a d-c motor
I_M = main winding current
I_C = control winding current
I_{C1} = positive-sequence component of I_C
I_{C2} = negative-sequence component of I_C
I_S = stator current balanced polyphase
I_a = armature current in a d-c motor
R_S = stator resistance
R_R = rotor resistance
X_S = stator leakage reactance
X_R = rotor leakage reactance
G = exciting circuit conductance
B = exciting circuit susceptance
S = slip for balanced polyphase
S_1 = positive-sequence slip, actually the same as S
S_2 = negative-sequence slip $=2-S$
Z_1 = total positive-sequence impedance as measured at the terminals (or calculated from equivalent circuit for balanced polyphase) with $S=S_1$
Z_2 = total negative-sequence impedance as measured from the terminals (or calculated from the equivalent circuit for balanced polyphase) with $S=S_2$
Z = total impedance with rotor blocked
Z_C = external impedance in control winding circuit
R_a = armature resistance of a d-c motor
k_t = developed torque per ampere
k_v = generated volts per rpm
N = rpm
T = net developed torque
T_0 = net developed torque at zero speed
T_{B1} = developed torque for balanced polyphase operation at slip of S_1
T_{B2} = developed torque for balanced polyphase operation at slip of $2-S_1$
T_1 = developed positive-sequence torque
T_2 = developed negative-sequence torque
T_B = developed torque at zero speed with balanced polyphase voltage applied
k_{bM} = breadth factor of main winding
k_{bC} = breadth factor of control winding
k_{pM} = pitch factor of main winding
k_{pC} = pitch factor of control winding
N_M = number of turns on main winding
N_C = number of turns on control winding
c = effective turns ratio between main winding and control winding

Discussion

S. Davis (Arma Corporation, Brooklyn, N. Y.): By making assumptions which apply specifically to the 2-phase, servo-type motor, Mr. Koopman has developed a simple set of formulas, which enables the application engineer to predict, from manufacturer's data, the performance characteristics of these motors under varied conditions of use.

The formulas, because of their simplicity, also are useful to the designer in checking performance with given circuit parameters. The clear statement of the criterion for avoiding single-phase operation of a servomotor is particularly helpful.

Mr. Koopman concerns himself primarily with the "drag-cup" motor. It should be pointed out that in the very small sizes, equally high torque to inertia ratios can be achieved by using more conventional rotors of relatively small diameter in comparison with the frame size. This design generally requires less power in the control field, because a smaller air gap is possible, although more care must be taken in design to avoid single-phase operation.

The assumption of negligible leakage reactance of the drag cup has been borne out by the experience of the writer.

Mr. Koopman indicates a procedure for measuring primary leakage by means of a search coil properly placed in the air gap. It is of considerable importance in this to distinguish between the fundamental and harmonic components of air-gap flux distribution. A full-pitch undistributed search coil, for example, would measure total air-gap flux, rather than the fundamental space component, including fluxes which properly are part of the differential leakage. In small motors having few slots per pole per phase, the differential leakage may be a large part of the total, and serious errors may result. The writer would be very interested in learning the results of such measurements.

S. S. L. Chang (Robbins and Myers, Inc., Springfield, Ohio): Mr. Koopman brings out some very interesting and significant relationships between the motor constants and the speed-torque characteristics. His paper is valuable to both servo and motor engineers. However, a more straightforward and exact analysis can be made by using the cross-field theory. For instance, one of the results of the cross-field analysis is that with zero-control-phase electromotive force, a motor would develop negative torque at all speeds if and only if $R_R > |Z_3|$, where Z_3 is the impedance shown in Figure 2A of the discussion.

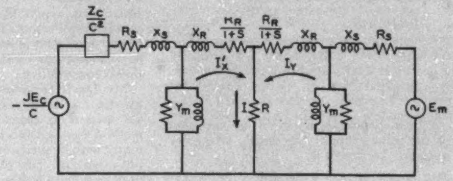
The cross-field theory equivalent circuit[1] is shown in Figure 1 of the discussion, in which the same symbols are used except that S stands for the ratio of the actual speed to synchronous speed instead of the slip. The motor torque is given by equation 31.

Figure 1. The equivalent circuit for the 2-phase servomotor

On this diagram

$$R=\frac{SR_R}{1-S^2}$$

$$S=\frac{\text{actual speed}}{\text{synchronous speed}}$$



Y_m represents the magnetizing admittance. All the motor constants are in main winding terms

$$T=RI^2+\frac{2R_R}{1+S}I_x'I_y\cos(I_x',\ I_y)\quad\text{synchronous watts}\qquad(31)$$

The control-phase electromotive force is multiplied by $-j$. In case the actual control-phase electromotive force and the main-winding electromotive force are at an angle of 90 degrees, the two voltage sources shown on the equivalent circuit would be in phase.

Applying Thevenin's theorem to the circuit of Figure 1 of the discussion, it reduces to that of Figure 3 of the discussion. The impedances $\boldsymbol{Z}_3$ and $\boldsymbol{Z}_4$ are defined in Figure 2 of the discussion. The voltages $\boldsymbol{E}_3$ and $\boldsymbol{E}_4$ are given by the following equations

$$\boldsymbol{E}_3=-\frac{j\boldsymbol{E}_c}{c}\times\frac{1}{1+\boldsymbol{Y}_m\left(R_s+jX_s+\frac{\boldsymbol{Z}_c}{c^2}\right)}$$

$$\boldsymbol{E}_4=\frac{\boldsymbol{E}_m}{1+\boldsymbol{Y}_m(R_s+jX_s)}$$

The behavior of any servomotor, with or without external impedance, is fully represented by this 2-mesh circuit.

Take as a numerical example, the motor analyzed by Mr. Koopman with $\boldsymbol{Z}_c=200$. The impedances and voltages are calculated to be

$\boldsymbol{Z}_3=22.6+j80 \qquad \boldsymbol{E}_3=22.5k\underline{/48.6^\circ}$

$\boldsymbol{Z}_4=9.85+j57 \qquad \boldsymbol{E}_4=33.3\underline{/12.8^\circ}$

At slip 0.4 or $S=0.6$, the solution of the 2-mesh circuit is

$\boldsymbol{I}_x'=0.1382k\underline{/12.3^\circ}-0.1092\underline{/-42.4^\circ}$

$\boldsymbol{I}_y=0.228\underline{/-18.3^\circ}-0.0738k\underline{/-6.6^\circ}$

For $k=0.5$

$\boldsymbol{I}_x'=-0.0131+j0.0883$
$\boldsymbol{I}_y=0.180-j0.0674$
$\boldsymbol{I}=0.167+j0.021$
$T=93.7\times0.168^2-2\times62.5(0.0131\times 0.180+0.0883\times0.0674)=1.6$ synchronous watts

To obtain a general expression of motor torque with zero-control-phase electromotive force, $\boldsymbol{E}_3=0$. The currents $\boldsymbol{I}_x'$ and $\boldsymbol{I}_y$ can be expressed in terms of $\boldsymbol{I}$

$$\boldsymbol{I}_x'\left(\frac{R_R}{1+S}+\boldsymbol{Z}_3\right)=-\boldsymbol{I}\frac{SR_R}{1-S^2}$$

$$\boldsymbol{I}_x'+\boldsymbol{I}_y=\boldsymbol{I}$$

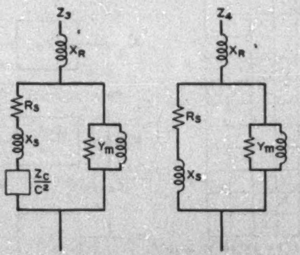


Figure 2. Definitions of Z_3 and Z_4

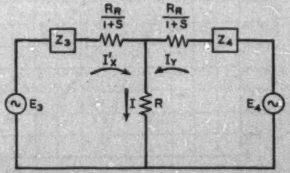

Figure 3. The simplified equivalent circuit

Substituting these expressions in equation 31 and simplifying the result, it yields

$$T=\frac{I^2R_RS}{1-S^2}\times\frac{|Z_3|^2-\dfrac{R_R^2}{1-S^2}}{\left|\mathbf{Z}_3+\dfrac{R_R}{1+S}\right|^2}\quad\text{synchronous watts}\qquad(32)$$

From equation 32, it is evident that

1. if $R_R>|Z_3|$,

torque is negative at all speeds

2. if $R_R<|Z_3|$,

torque is positive in the range

$$0<S<\sqrt{1-\frac{R_R^2}{|Z_3|^2}}$$

The cross-field theory gives an expression of the peak value of the double frequency pulsating torque, it is

$$T_p=RI|\mathbf{I}_x'-\mathbf{I}_y|\qquad(33)$$

For the numerical example cited, it is

$$T_p=93.7\times0.168\times|-0.193+j0.156|$$
$$=3.90\text{ synchronous watts}$$

The application of the cross-field equivalent circuit does not require any knowledge in electrical machinery. It also can be constructed in control winding terms and integrated into the amplifier circuit.

1. The Equivalent Circuit of the Capacitor Motor, S. S. L. Chang. *AIEE Transactions*, volume 66, 1947, pages 631–40.

R. J. W. Koopman: The writer is grateful to Mr. Davis for showing that his experience with 2-phase servomotors checks with the writer's deductions in the paper. Regarding the question of emphasis on the "drag cup" motor, the writer desires to state that drag cup motor constants were used in constructing the illustrative curves in the paper because they produced a more striking example of the phenomenon of negative torque on single phase than other typical constants which were available. When the usual assumptions[1] are met in like degree, the formulas developed apply equally as to "drag cup" motors as to those of more conventional construction.

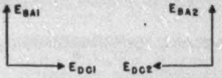

Figure 5. Components of voltage applied to servomotor through external impedances

Mr. Davis' last point concerns the experimental results of the search coil method for measuring primary impedance. This method was used on a small 2-phase drag cup motor with 2-layer winding consisting of one full-pitch coil per phase per pole. (The drag cup type was used because of a convenience which will be obvious.) The search coil was a full-pitch coil consisting of about ten turns of fine wire placed in the small openings between the teeth.

A terminal voltage V' applied to the stator with the rotor removed (simulating the no load condition for a conventional design) produced a voltage E on the search coil. With the rotor replaced and blocked, a different voltage V'' was required to produce the same E. From these readings, and current and phase-angle readings, the parameters for the equivalent circuit were calculated. From the equivalent circuit thus determined, speed-versus-torque curves were calculated in the usual manner, that is sinusoidal space distribution of flux was assumed. This curve then was corrected for the effect of the space harmonics. It was assumed that the flux wave produced by each phase acting alone was flat topped because of the single full-pitch coil winding. The amplitudes of the space harmonics fluxes are $1/n$ where n is the order harmonic and always odd. The correction was made by taking the harmonic torques as $1/n^2$ times the fundamental torque at the same slip and combining these with the fundamental, due regard being given to direction. The writer has not explored thoroughly the theoretical details involved, but the curve of Figure 4 of the discussion will show that good practical results were obtained in the instance cited.

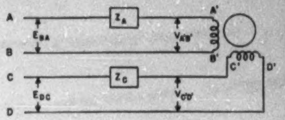

Figure 6. Servomotor circuit

The author also is grateful to Mr. Chang for bringing to his attention an equivalent circuit from which a quantitative criterion regarding single-phase operation is readily obtained. This circuit also facilitates the calculation or the actual measurement in a laboratory equivalent circuit of motor terminal impedances for various conditions of operation which is important in the application of motors in servomechanisms.

However, there also are some advantages over Mr. Chang's circuit possessed by the one given in a supplement to this closure and which is based on the revolving field theory and the induction motor equivalent circuit for balanced operation. If the latter were set up in the laboratory, torque could be obtained by the recording of two currents and two resistances whereas if Mr. Chang's circuit were used three currents, two resistances and one phase angle between currents would have to be recorded.

It has been known for years that the cross-field theory and the revolving-field theory of the single-phase induction motor lead to exactly equivalent results when equivalent design constants are used,[2] and more recently this argument has been extended to capacitor motor analysis.[3,4] Mr. Chang forged another link in the chain of this evidence when he calculated a performance point by means of formulas based on the cross-field theory and checked the calculations made by means of the formulas in the paper which are based on the revolving-field theory. Therefore, Mr. Chang's statement regarding a more "exact analysis" must be interpreted with care.

The question of which analysis is the more

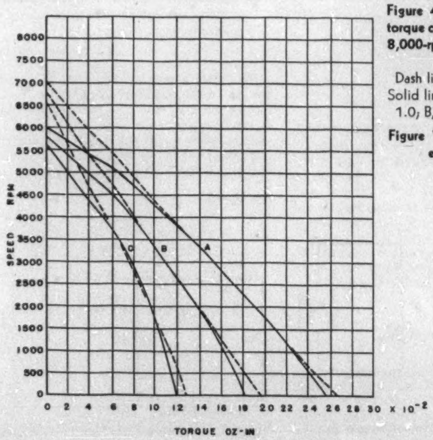

Figure 4 (left). Speed-versus-torque curves for small 2-phase 8,000-rpm synchronous speed servomotor

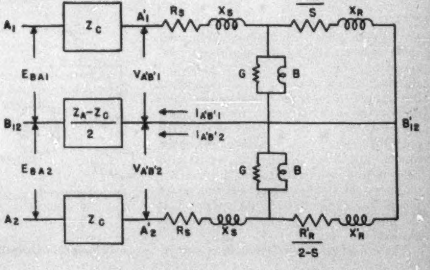
Figure 7 (right). Servomotor equivalent circuit



straightforward in general is a matter of opinion as has been pointed out in the literature.[4] It is the writer's opinion that an analysis, such as given in the paper, which is based on the equivalent circuit for the induction motor as it has been taught in electrical engineering schools for many years and symmetrical component theory, which also has been widely taught, is more straightforward than an analysis based on the cross-field theory.

SUPPLEMENT TO CLOSURE

In the paper under discussion it is obvious that the performance calculations for the more difficult cases are rather formidable even with the aid of a vector slide rule or calculating machine. Much time could be saved if an equivalent circuit were set up in the laboratory and direct measurements made. If the circuit were set up on a per unit[5] basis, a limited range of impedance units could be used to cover a range of ratings.

Such a circuit, quite similar to those developed by Kron[6,7] for the capacitor motor was derived by the writer from ordinary symmetrical component theory and the usual equivalent circuit for the induction motor on balanced voltages. An article on this was sent in to AIEE for review after the paper under discussion was preprinted. Slides showing the circuit were used by the author in his presentation of the paper under discussion. The essential details of this article are given here at the request of the reviewing committee.

All the formulas in the paper can be derived from this circuit.

The same assumptions regarding superposition, constancy of permeance, circuit balance, and sinusoidal time variation of current and voltage are made as in the paper. Fluxes also are assumed to have a sinusoidal space distribution as the inclusion of the space harmonics would lead to a cascade of equivalent circuits.[8]

DERIVATION OF AN EQUIVALENT CIRCUIT FOR 2-PHASE SERVOMOTORS

Method. The method of analysis consists in writing the symmetrical components of the applied voltages in terms of the voltage drops produced by positive- and negative-sequence currents flowing through the external impedances[9] and the positive- and negative-sequence terminal voltages on the motor.

These latter voltages are equal to the products of the respective sequence currents by the sequence impedances calculated from the "exact" induction-motor equivalent circuit using slip, s, for the positive sequence and 2-s for the negative sequence slip.[10]

Basic Equations. Unbalanced 2-phase voltages may be resolved into several equivalent systems.[10] However, the system chosen here is that shown in Figure 5 of the discussion.

When symmetrical components of voltage are applied directly to the terminals of the servomotor, they are related to the symmetrical components of current by the following equations.

$$V_{A'B'1}=I_{A'B'1}Z_{A'B'1} \tag{34}$$

$$V_{A'B'2}=I_{A'B'2}Z_{A'B'2} \tag{35}$$

where $V_{A'B'1}$ and $V_{A'B'2}$ are respectively the positive- and negative-sequence components of terminal voltages referred to the winding designated as $A'B'$ and with circuit direction of application designated by double-subscript notation,[12,13,14] $Z_{A'B'1}$ and $Z_{A'B'2}$ are the motor impedances to the positive- and negative-sequence components of current, $I_{A'B'1}$ and $I_{A'B'2}$.

Referring to Figure 5, the voltages applied to the complete system, servomotor and external impedances, may be resolved as follows[15]

$$E_{BA1}=\frac{E_{BA}+jE_{DC}}{2} \tag{36}$$

$$E_{BA2}=\frac{E_{BA}-jE_{DC}}{2} \tag{37}$$

The terminal voltages may be similarly resolved as follows

$$V_{A'B'1}=\frac{V_{A'B'}+jV_{C'D'}}{2} \tag{38}$$

$$V_{A'B'2}=\frac{V_{A'B'}-jV_{C'D'}}{2} \tag{39}$$

The currents may be resolved by means of equations paralleling 38 and 39. From Figure 6 of the discussion

$$E_{BA}=I_{A'B'}Z_A+V_{A'B'} \tag{40}$$

$$E_{DC}=I_{C'D'}Z_C+V_{C'D'} \tag{41}$$

From equations 36, 40 and 41,

$$E_{BA1}=\frac{I_{A'B'}Z_A+jI_{C'D'}Z_C+V_{A'B'}+jV_{C'D'}}{2} \tag{42}$$

Substituting an equivalent value for the right-hand voltage terms from equation 38

$$E_{BA1}=\frac{I_{A'B'}Z_A+jI_{C'D'}Z_C}{2}+V_{A'B'1} \tag{43}$$

Since the currents may be resolved into their symmetrical components,

$$E_{AB1}=(I_{A'B'1}+I_{A'B'2})\frac{Z_A}{2}+ j(I_{C'D'1}+I_{C'D'2})\frac{Z_C}{2}+V_{A'B'1} \tag{44}$$

From Figure 5

$$jI_{C'D'1}=I_{A'B'1}$$

$$jI_{C'D'2}=-I_{A'B'2}$$

hence

$$E_{BA1}=I_{A'B'1}\left(\frac{Z_A+Z_C}{2}\right)+ I_{A'B'2}\left(\frac{Z_A-Z_C}{2}\right)+V_{A'B'1} \tag{45}$$

Similarly

$$E_{BA2}=I_{A'B'1}\left(\frac{Z_A-Z_C}{2}\right)+ I_{A'B'2}\left(\frac{Z_A+Z_C}{2}\right)+V_{A'B'2} \tag{46}$$

It is evident that equations 45 and 46 are expressions of Kirchhoff's voltage law written around the two loops of the circuit shown in Figure 7 of the discussion. In applying the voltages E_{BA1} and E_{BA2} to the servomotor equivalent circuit they must act in the circuit direction indicated by the double subscripts.

The elements in Figure 7 of the discussion, R_S, X_S, R_R, X_R, G and B are respectively stator resistance and reactance, rotor resistance and reactance and the components of exciting admittance all for the servomotor considered as an ordinary polyphase induction motor. The symbols for rotor resistance and reactance in the lower part of the diagram are primed to indicate the possible desirability of making a correction in these values due to the higher frequency of the negative-sequence rotor currents.

The positive-sequence torque per phase in synchronous watts is the power in the resistive element, R_R/S, in the upper part of the circuit of Figure 7. The negative-sequence torque per phase is found from the power in the corresponding element $R_R/(2-S)$ in the lower half of the circuit. Net torque per phase is the difference between these two torques.

The Thermal Movement of Moisture in Soil

A. S. MICKLEY
ASSOCIATE AIEE

THIS paper develops a theory of moisture movement in soils under thermal gradients and demonstrates confirmation of test data published previously. A formula is derived to determine moisture movement quantitatively so that the precise effect on underground cable heating can be evaluated.

It has long been known that when a moist soil is subjected to a temperature gradient, the moisture will have a tendency to move in the direction of heat flow.

This migration will not continue until all of the moisture has been removed, but will cease after equilibrium conditions have been established. This phenomenon is of considerable interest in cable heating studies, because the thermal conductivity of the earth in the heat field involved will decrease as moisture is lost. If the loss is appreciable, it must be taken into consideration in temperature calculations.

The mechanism of moisture movement is thought to be due primarily to surface tension, although vapor movement also may be involved.

Surface Tension Movement

The moisture in the soil is considered to be held in droplets between soil particles, much as shown in Figure 1(a). The droplets are kept in place by surface tension forces, which must be in equilibrium in all directions. The irregular spaces between the soil particles give each moisture droplet an opportunity to take the shape necessary to satisfy the conditions of equilibrium.

To understand the mechanism, consider first a droplet of moisture between two horizontal flat plates as shown in Figure 1(b). The forces along the AB axis would be equalized as follows

$$F_A = F_B$$

or

$$4R_AS_A = 4R_BS_B \qquad (1)$$

where S is the surface tension in dynes per centimeter and R is the radius in centimeters. The factor 4 takes into account the integration of the A and B axis components of the surface tension radial forces, as well as the combined effects of the top and bottom meniscuses. Equation 1 is really an adaptation of the classical formula of force on a semicircular ring under normal pressure.

Force = diameter × unit pressure

Assume next that a temperature gradient is introduced so that the temperature at A is greater than at B. Surface tension varies with temperature T by the following relationship

$$S = S_0(1 - aT) \text{ dynes per centimeter} \qquad (2)$$

where S_0 and a are constants.

The surface tension at A will now be less than at B. To restore equilibrium the radii must change, R_A becoming greater and R_B less. This produces a distortion as indicated by the dotted line in Figure 1(b). The greater the gradient, the greater the distortion, hence we can write the relation

$$\text{Distortion} \propto \frac{dT}{dx} \qquad (3)$$

where dT/dx is the temperature gradient in degrees centigrade per centimeter.

Now in the course of distorting, the droplet may meet another droplet and merge to form a new, larger droplet. When a merger takes place, the surface tension forces are completely upset. The new droplet must seek to re-establish equilibrium by moving until it finds lodging in a crevice system whose shape produces the necessary equalization. It may even find another droplet in the course of this movement and have another merger. The resulting droplet must then start all over again to find equilibrium. It continues to move, therefore, until it can conform to the proper shape without touching off another merger in the process.

The movement of a droplet seeking equilibrium may be in any direction. In a temperature gradient field, however, the surface tension forces will be stronger in the cold direction. Among a large selection of droplets, therefore, the net effect will be a movement from hot to cold.

The distortion in a droplet, relation 3, is one factor. Its effect is modified, however, by the probability that a given amount of distortion will cause merger with an adjacent droplet. To develop this additional factor, assume a triangular arrangement of uniform soil particles as shown in Figure 1(c). Assume that the space between any two soil particles is a possible container of a droplet. A few spaces have been numbered for convenience. Take space number 1. This may be either occupied or unoccupied by a moisture droplet. The probability of its being occupied is

$$P_o = \frac{\text{total number of droplets}}{\text{total number of spaces}} = \frac{M_t}{F} \qquad (4)$$

where M_t is the initial moisture content and F is the field capacity, or the moisture content at saturation, both expressed in per cent of dry weight of soil.

Now consider the probability of the moisture in space 1 merging with the moisture in space 2. Any two adjacent

Paper 49-83, recommended by the AIEE insulated conductor committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted November 10, 1948; made available for printing December 17, 1948.

A. S. MICKLEY is with the Philadelphia Electric Company, Philadelphia, Pa.

The author wishes to acknowledge the helpful suggestions of A. H. Kidder, J. H. Neher and W. O. Smith.

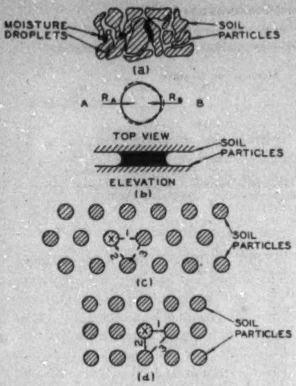

Figure 1. Soil particle moisture droplet relationships

spaces may be chosen. For a merger both must be occupied, the probability of which is $(M_i/F)^2$. If, however, spaces 1 to 3 are all occupied simultaneously as well as the spaces above and below particle X, this merger between 1 and 2 cannot take place, since they are already joined within an established water mass. The probability of this, $(M_i/F)^6$, must be subtracted from the total probability. The merger probability is therefore

$$P_m = \left(\frac{M_i}{F}\right)^2 - \left(\frac{M_i}{F}\right)^6 \qquad (5)$$

This relationship is seen to hold for both the triangular and rectangular structures of Figure 1(c) and 1(d).

The distortion and merger probability effects will be further modified by the particle size and by the distribution of particles of various sizes within a soil. These factors are taken care of by a constant of proportionality k, which is determined by test.

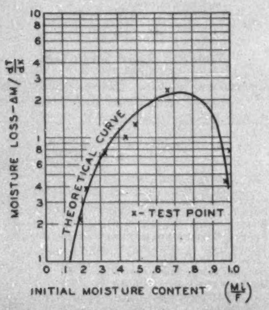

Figure 2. Thermal movement of soil moisture. Theoretical curve of surface tension movement plotted against data of Smith[1] for Barnes loam, horizon C

Relationships 3 and 5 are multiplied by the constant of proportionality to give the total movement equation

$$\Delta M = k\frac{dT}{dx}\left[\left(\frac{M_i}{F}\right)^2 - \left(\frac{M_i}{F}\right)^6\right] \qquad (6)$$

where

ΔM = moisture lost in per cent of dry weight (final moisture content $- M_i$)
M_i = initial moisture content in per cent of dry weight or the moisture content previous to application of a thermal gradient
F = field capacity of the soil in per cent of dry weight. (The moisture content of the soil at saturation is required here. There are a number of means of determination used by soil scientists based on various laboratory techniques. Either the field capacity or the moisture equivalent of a soil is satisfactory for use.)
dT/dx = temperature gradient degrees centigrade per centimeter
k = constant of proportionality, per cent centimeters per degree centigrade

Hot Radiator versus Cold

Equation 6 describes the tendency of soil moisture to move away from a hot radiator, such as a buried cable. It will not describe the effect of moisture collection around a radiator cooler than the surrounding soil, such as a heat pump circulating coil. In this case the coil surface forms a barrier which prevents any further moisture movement in the cold direction. The moisture accumulation cannot build up beyond the field capacity, however, since any moisture in excess of the field capacity will percolate down to the water table by gravitational flow.

Test Confirmation

W. O. Smith[1] has made very careful measurements of soil moisture movement under a thermal gradient, but has not attempted in published work to analyze his data on a mathematical or theoretical basis.

Smith's method was to place a soil sample between two parallel plates of different temperature. Measurements of soil moisture before and after 72 hours' exposure to the temperature gradient were made at three different points: the hot face, the cold face, and half way between. The movement of moisture away from the hot face and toward the cold face fits equation 6 quite well. The data plotted in Figure 2 are a typical example of one of the 18 samples Smith tested. In this particular soil, both the hot face measurements and the center measurements fit the curve. The cold face measurements do not fit, since the cold plate forms a barrier which causes the moisture to pile up artificially. In several soil samples, only the hot face measurements fit the theoretical curve, apparently because the cold barrier accumulation backs up into the center measurement point.

An analysis of the data presented by Smith[1] is given in Table I. From this it will be seen that the maximum value of k is 9.6 per cent centimeters per degree centigrade. Since the maximum value of equation 5 is 0.32, the maximum value of ΔM is 3.1 per cent per degree centigrade per centimeter.

Vapor Movement

No consideration of moisture movement would be complete without a discussion of the possibility of transfer by means of vaporization and condensation. To study this problem in soil, we must review some fundamental laws governing moist air:

1. A flat surface of water has a definite vapor pressure at a given temperature.
2. The vapor pressure above a curved liquid surface is less than or greater than the flat surface vapor pressure, depending upon whether the surface is concave or convex. The surface presented by water in a porous body is concave. For a concave surface the relationship is

$$V_P\ (\text{concave}) = V_p\ (\text{flat}) - \frac{v}{l-v}\,\frac{2S}{R} \qquad (7)$$

where

V_P = vapor pressure
v = vapor density
l = liquid density
S = surface tension
R = surface radius

3. The saturation point of a gas depends on Dalton's law of partial pressures, and the vapor content at saturation can be written

$$V = K\frac{P_s}{P - P_s} \qquad (8)$$

where

V = vapor content, pounds per pounds of dry air
K = constant
P_s = vapor pressure of liquid evaporating into gas
P = pressure of the gas and vapor mix

In a porous body, the surface tension forces are strongest in the smallest pores. The addition of a little moisture to a porous body will therefore tend to fill the smallest pores first. Looking at equation 7, we see then that the lower the moisture content, the lower R (radius of pore), and

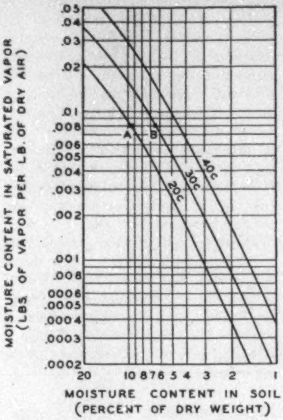

Figure 3. Moisture–vapor equilibrium chart for Sudan heavy clay[2]

Table I. Moisture Movement Constants From Smith

Values of *k* in Per Cent Centimeters Per Degree Centigrade

Soil Type	A	A_1	A_2	B	B_1	B_2	B_3	C
Barnes loam	4.2				3.3	4.2		7.0

†Inconclusive.

therefore the lower the vapor pressures within the porous body. By equation 8, the lower vapor pressures produce lower moisture contents in the saturated vapor. This is precisely what happens, and exact data are published[2] for certain African soils. Figure 3 is a calculated curve of moisture content of saturated vapor within moist soil in equilibrium with contained moisture, taking the published data.

For vapor equilibrium to prevail between two points in soil the following conditions must exist:

1. The partial pressure of vapor in air next to a moisture droplet must be equal to the vapor pressure of the surface of the droplet. In this case the air will be saturated with respect to the droplet.
2. The pressures of the air and vapor mixes at the two points must be equal.
3. The moisture contents of the saturated vapors must be equal.

If the two points are at different temperatures, they will satisfy these conditions if they are located on the same horizontal line in Figure 3. Thus we see that *Sudan A* at 20 degrees centigrade and 9.5 per cent moisture content can be in vapor equilibrium with *Sudan B* at 30 degrees centigrade if *B* has 6.5 per cent moisture content. There is, therefore, a tendency for moisture to move away from a hot body under a thermal gradient, but this can reach an equilibrium when the moisture content of the hot area has been sufficiently reduced.

Most investigators have felt that the vapor movement is negligible, or at least very slow. The effects may well be imperceptible in extremely fine grained soils, such as clay. In these cases the resistance to vapor flow is probably greater because of smaller passages.

Except for flow resistance, Figure 3 must always be satisfied for complete equilibrium to exist. Since the surface tension movement is likely to be quite rapid, this undoubtedly is greater initially. It can be seen that this movement is in the right direction for obtaining vapor equilibrium. The portion of vapor equilibrium achieved by surface tension movement may be large, and therefore the remaining vapor movement may be slight. An indication of this is that although Smith's tests were made on relatively coarse grained soils, his 72-hour data check the surface tension movement theory alone.

Application

Electric utilities, with large investments in underground cables, have for many years feared the effects of moisture migration on cable temperatures. In the absence of a means to evaluate this effect, they have limited the temperature of cables and ducts in direct contact with the earth, in the hope that a serious runaway of moisture would be prevented. This temperature limit is usually set at 50 or 55 degrees centigrade.

J. H. Neher[3] has applied equation 6 to the heat field of a buried cylinder for the purpose of providing a method to determine the effect of moisture movement on actual cable problems. The application of the method to two typical examples is given in Table II. These values are based on a movement constant of 9.6, the maximum value listed in Table I, and show that the effect is of little importance.

One should not expect that the moisture movement phenomenon discussed in this paper would be applicable at very high temperature gradients. Little is known about the critical temperature gradient, beyond which moisture will migrate until only dry earth remains. The author has had but one experience with this drying-out effect. This occurred as a result of an accidental overload applied to a heated sphere buried in clay loam. In this instance the drying-out effect started at 65 degrees centigrade and at a surface temperature gradient of 6.6 degrees centigrade per centimeter, but proceeded in an orderly fashion, with the effective earth resistivity stabilizing at a new level approximately 30 per cent greater than the original one. A summary

Table II. Examples of Moisture Movement Effects

	6-Cable Duct Bank	8-Inch Pipe
Maximum heat flow, watts per foot	30	38
Buried depth to center, inches	43	40
Initial earth resistivity, degrees centigrade centimeters per watt	75	60
Maximum temperature gradient, degrees centigrade per centimeter	.45	1.17
Temperature rise of structure, centigrade		
(a) Neglecting moisture movement	25.2	35.7
(b) With maximum moisture movement	26.0	37.5
(c) Per cent increase due to moisture movement	3.2	5.0

Table III. Buried Sphere Tests

Comparison of One Sphere Which "Ran Away," With One That Did Not

	"Run-away" Sphere	Stable Sphere
Sphere diameter, inches	6	8
Buried depth to center, inches	48	48
Watts	58	125
Ambient temperature, centigrade	19	23
Temperature at which drying-out started, centigrade	65	....
Ultimate temperature, centigrade	86	78
Earth resistivity, centigrade centimeters per watt		
At start	86.5	61
Ultimate	114	62
Temperature gradient at sphere surface, degrees centigrade per centimeter		
Before runaway	6.6	6.0

of this case is given in Table III, together with another case of operation without drying-out at 78 degrees centigrade.

Conclusions

1. The net direction of moisture movement in earth is from warm toward cool regions in the heat field surrounding a given underground heat radiator, or heat collector.

2. Moisture movement ceases when and if the resulting moisture distribution satisfies the conditions of surface tension and vapor pressure equilibrium at the temperatures and temperature gradients finally attained.

3. There is undoubtedly a critical temperature gradient for each soil, such that the soil will dry out altogether in any region exposed to an equal or greater temperature gradient. One unintentional test in clay loam indicated the critical gradient for that situation to be approximately six degrees centigrade per centimeter, or well beyond the probable limits of normal underground conduit design practice.

4. At normal maximum temperature gradients of less than two degrees centigrade per centimeter, the moisture movement effects appear to be almost negligible.

5. Vapor movement in the soils investigated accounts for very little of the net moisture movement in the vicinity of heated surfaces. Analysis of this factor, however, suggests that it might be found to account for appreciable moisture movement through very coarse-grained media such as gravel or crushed stone.

6. For underground heat collector coils, such as may be used with heat pumps, the cold surface of the coil or its frozen environment should be expected to form a liquid and vapor barrier in the vicinity of which moisture will accumulate in the liquid state until the earth becomes saturated. If there is additional moisture movement thereafter, the excess liquid will percolate downward gravitationally and away from the coil. It is therefore possible that the use of very coarse backfill around such coils might enhance considerably their heat collecting capacity.

Discussion

Herman Halperin (Commonwealth Edison Company, Chicago, Ill.): The author has focused attention on one important point in the heating of underground conduits and of pipes containing power cable. This paper, as well as the companion article by Neher,[1] is especially valuable at the present time, because the installation costs for underground conduit and pipes have risen by more than 100 per cent in the past ten years. It, therefore, becomes very necessary to know just how great the allowable heating may be in order to utilize conduit and pipes to the fullest possible.

Under the heading of "Application" the author mentioned a temperature limit of 50 or 55 degrees centigrade for cables and ducts in direct contact with the earth as being the limits in general use. In a paper I presented in 1942 "Load Ratings of Cable—II," I mentioned limits of 55 or 60 degrees for the duct temperature for normal operation and 5 degrees higher for emergency operation.[2] It seems to C. A. Bauer and myself that for the variety of soil conditions found in Chicago it is difficult to set an exact general limit.

For one set of conduits containing generator leads operating at a high load factor, we have set a limit of 70 degrees for the duct temperature and we have followed that location closely over the past several years; so far, with temperatures of about 65 degrees or so there has developed no run-away condition. The soil there is a sandy loam. For another location where there is heavy clay around the conduits, we have set a limit of 55 degrees centigrade for the duct temperature for normal operation. In the summer of 1948 there was a case of one conduit, having clay and loam fill around it, where a runaway condition tended to develop when the duct temperatures got to about 60 degrees centigrade. It was necessary to flood this conduit twice during the summer and also to install means for keeping the conduit wet into the fall.

It might be well if the author would discuss further the apparent inconsistency between the deductions that may be drawn between Table II and Table III. Table II shows only a three per cent increase in the temperature rise of an underground structure due to moisture movement, whereas Table III shows a change in the earth resistivity for the "run-away" sphere of 30 per cent. Furthermore, the heating load in Table III for the run-away sphere was about 1/6th less in watts per square inch of sphere surface than for the stable sphere.

Based on somewhat meager data, it seems to us that the limit of two degrees centigrade per centimeter given in conclusion 4 as the limit where moisture movement effects appear to be almost negligible may be a little too high.

C. G. Mansfield (Water and Power Department, City of Los Angeles, Los Angeles, Calif.): The author has developed a fascinating hypothesis into an interesting and at least superficially plausible explanation of the migration of soil moisture along a temperature gradient. A more critical study of the assumptions and steps in this development raise substantial doubts as to whether the resulting formula is a true representation of the actual process, or whether the check with certain of the experimental data results from coincidence, aided by a rather liberal adjustment of the constant *k*, and elimination of the more unfavorable cases on the ground of artificial piling up of moisture at the cold end; an explanation which would appear to be acceptable only if the soil in that region becomes saturated. Following are some of the points which seem to the writer to be of doubtful validity, or to need further clarification or support.

One basic fault in the proposed theory is best visualized in the case of a homogenous soil with initially uniform moisture distribution, subjected to a uniform temperature gradient between parallel isothermal surfaces. Since the action at any point depends only on the thermal gradient and not at all on temperature, the moisture movement in all layers should be the same, and the end result would be a thin dry layer at the warm surface, a saturated layer at the cold surface having a thickness varying with the initial moisture content, but no change in the moisture content of the layers between them. This, I believe, is not in agreement with the observed facts.

The whole development is founded on the assumption that the moisture exists as discrete droplets presumably separated by dry surfaces, since if they were connected by surface films they would not wait for a droplet distortion to bring them into contact before merging. This condition would eliminate any possibility of capillary movement toward plant roots or toward an exposed surface at which evaporation is occurring. In fact, dryout by surface evaporation probably could not occur, since the temperature gradient established by sunshine or atmospheric temperature rise would drive the moisture deeper into the ground rather than bring it to the surface. Such an assumption, therefore, fairly demands further support, either by direct verification or by some rational explanation of the manner in which such a moisture distribution can be established. After the "gravitational water" has drained from an initially saturated soil, it is not at all clear why, in the process of further drying out by loss of moisture from the capillary spaces, the moisture remaining therein should break up into a large number of small droplets against their powerful tendency to reunite when brought into light contact by a minor distortion of shape. The two concepts seem directly contradictory, and we are required to believe that the initial dryout is accompanied by a decrease in average droplet size while a subsequent, or even simultaneous, local dryout due to a temperature gradient is accompanied by an increase in average size.

It seems reasonable to expect some distortion of a droplet due to nonuniform temperature, but the fact that this distortion, (expressed in some unit which the author does not define), increases with the temperature gradient does not necessarily mean that it is directly proportioned thereto as indicated in relations (3) and (6). In fact, both the geometric complexity of the droplet and the relation expressed in equation 2 raise considerable doubt as to the accuracy of that simple relationship. Incidentally, it seems very improbable that the picture of this distortion shown by the dash line in Figure 1 (b) can be correct since with a presumably uniform temperature gradient from left to right, the radius of curvature first decreases, then increases (at the tangent), and again decreases at the right end.

Numerous efforts to confirm the reality of a droplet distortion of significant magnitude have all given negative results. Droplets of various sizes were trapped between glass plates separated by one to three mils and observed through a 100x microscope while a temperature gradient was applied by placing a warm metal block on one end of the slide. In some cases the gradient was high enough to start rapid evaporation from the droplet edges within 30 seconds. In no case was there any observable distortion of the circular form when the gradient was applied. Possibly this means only that important distortion is confined to much smaller droplets, but this places serious limitations on the effective displacement of moisture which can result. When two particles of liquid merge under surface tension forces following contact, the resulting droplet occupies a position between the original ones, it is not projected forward as from a gun. It is therefore difficult to imagine any average displacement of the original moisture much in excess of the distortion of the droplets. It is not at all clear, in fact, just how the merger process can add anything to the effective displacement inherent in the distortion of the original droplet. And if significant distortion occurs only in the very small droplets, the effective moisture displacement must be correspondingly small and wholly inadequate to account for the movement observed in practice.

The character of the final result is largely determined by the probability equation 5, the development of which I find far from convincing. From equation 4 it would appear that for the theoretical development, the droplets and spaces are all conceived to be of the same size. If this be true, then droplets occupying two adjacent spaces would already be in contact and so would make any further "merger" impossible just as effectively as would occupancy of all four adjacent spaces. If "occupancy" is so defined as to avoid this difficulty, then the ratio of the distance between nominally "adjacent" droplets to the distortion becomes an important factor which does not seem to be reflected in the equations. The probability of secondary and later mergers also fails to appear in the equation, although it must certainly vary with the moisture content and so cannot be covered by constant k. It seems reasonable to expect that the product of a distortion factor and the probability of a resulting merger, as in equation 6, would represent the amount of moisture taking part in such mergers, but it can hardly be correct to speak of such moisture as "lost." It is still there, and not much more than a droplet's width away from its original location.

Finally there is the element of time. It would be expected that a low viscosity liquid such as water should adjust itself to a change in surface tension within, at most, a few minutes after the thermal gradient is established rather than after several days or weeks.

In view of the many questionable points involved in the development of this theory, it would seem prudent to use it with extreme caution until the facts are more fully established.

W. A. Hadley (Columbia University, New York, N. Y.): Mickley should be congratulated on his very excellent paper. There has not been very much work done on thermally actuated moisture migration and few investigations, if any, have attempted to express the phenomena mathematically.

The author limits his analysis to heat sources and states that his work is not applicable to heat pumps because the circulating coil would form a barrier, preventing moisture from migrating in the cold direction. He asserts that any moisture in excess of field capacity would percolate by gravity down to the water table.

From the results published by C. H. Coogan in his report, "The Residential Heat Pump in New England," it would appear that this may not be the case. Calculated values of the field capacity for the soil surrounding this ground coil indicate a field capacity of 31 per cent on the dry basis. However, samples of frozen soil chipped from the soil around the coil after the test period were found to range from 30 per cent to as high as 40 per cent wet. Perhaps the water is trapped by freezing, which in turn produces small cracks allowing more water to migrate in and thus yield concentrations in excess of the field capacity.

To investigate the application of Mickley's equation to heat pump ground coils, a calculation was made based on Coogan's experimental work. The soil surrounding the pipe was divided into annular zones, and it was assumed that all of the moisture lost by each of these zones appeared in the frozen soil around the pipe. Using the experimental temperature gradients, and the initial moisture concentration of 25 per cent, these losses were evaluated.

If a conservative value of 7.0 is used for k, the constant of proportionality, the final wetness around the coil is calculated to be 31.5 per cent, which falls within the measured moisture contents of 30 to 40 per cent. If we use the maximum value of k reported by Mickley, that is, $k=9.6$, the final moisture content is 33.9 per cent, which is still at the conservative end of the measured values. Perhaps additional experimental work will further substantiate this paper and may reveal higher values for the proportionality constant.

So far the results from this paper are encouraging, and at the present time it is by far the best interpretation of this phenomenon.

A. S. Mickley: Halperin's discussion confirms the thesis of the author that there is no definite value of soil contact temperature which is generally applicable, and that the use of too low a value can result in the loss of much inherent load capacity. Halperin's method of exceeding 50 degrees centigrade where necessary and maintaining a careful watch is a practical answer to this situation. It is hoped, however, that this paper may be helpful in line design, and may be useful in pointing the way to further study of the many variables in this problem.

The apparent inconsistency between Tables II and III is partially explainable in terms of temperature gradient. The maximum gradient in Table III is 6.6 degrees centigrade per centimeter, compared with 1.17 degrees centigrade per centimeter in Table II.

In addition, the tables treat two types of heat fields, the cylindrical and the spherical, which respond differently to the same conditions.

The comparison of watts per square inch of sphere surface, which Halperin cites, should be used with care, since it is not a fundamental measure which accounts for all variables, such as sphere diameter and depth of burial. It is true, however, that calculation indicates that both spheres should have run away, although only one did.

The fact that one was stable indicates either the constant k was too high for the particular soil, or that the moisture content was not at the movement curve peak of 75 per cent saturation, but was either very low or very high. Since this particular sphere was buried near a river, the moisture content was probably very high.

Mansfield's comments are much appreciated, since they afford the opportunity of more complete discussion of certain of the assumptions. The questions will be taken up in the order in which they were raised, except for the first question on uniform moisture distribution which, in the interest of a logical development, will be taken up last.

The inference that the surfaces between droplets are wet is correct. All soil particles must be covered with a water film, known as hygroscopic moisture, before capillary moisture can form. The thickness of this film has been estimated at between 15 and 20 molecules. The presence of this thin connecting film, however, does not nullify the possibility of further contact between droplets.

The natural drying out of the soil is brought about by three forces: surface evaporation, plant absorption, and downward percolation. Evaporation moisture is said to reach the surface either by capillary rise through an unbroken column, or by vapor movement. It is now thought that the bulk of plant moisture is obtained through the extension of root hairs to tap the capillary water directly. If these prevailing agricultural theories are correct, it is not apparent that they are fundamentally inconsistent with the local drying process described in this paper.

Mansfield questions the validity of equation 3. If equations 1 and 2 are combined we may write the following relationship

$$R_A = R_B\left[1+\frac{dT}{dx}\left(\frac{ax}{1-aT_A}\right)\right]$$

where

x = droplet diameter

If distortion is defined as the difference in radii, then distortion equals

$$R_A - R_B = \frac{dT}{dx}\left(\frac{ax}{1-aT_A}\right)R_B$$

Since the values in the parentheses are constants for a given droplet, proportionality is indicated.

From the objection to the egg-shaped dashed line of Figure 1(b), it appears that it has not been made clear that equation 1 is an integration of all the normal force components along a given axis. Since the normal forces at the tangent have relatively weak components along the A-B axis, they are not major contributors to equilibrium. The adjustment of radii at the tangent is geometrically necessary in order that the figure may close.

Mansfield has difficulty in accepting distortion as the trigger, or initiating force of movement. Smith[1] has advanced the hypothesis of the trigger action of surface evaporation and condensation, which Mansfield observed under his microscope. While it seems virtually impossible to isolate the two triggers by observation in actual soil, it is entirely conceivable that both triggers are operative. A complete analysis of the evaporation and condensation trigger may also confirm the proportionality to temperature gradient indicated by the test data.

When Mansfield describes how a merged droplet occupies the space between the two original positions, he is presumably thinking of cases in which this space is large compared with the droplets. Where this is applicable, however, the shape of the intermediate location may not be compatible with equilibrium of surface tension forces As described in the paper, the droplet may then have to travel a considerable distance before finding a crevice system exactly suited to the re-establishment of equilibrium. This distance could conceivably be much greater than the droplet width implied by Mansfield.

Any sample of soil contains a very large number of particles and droplets. In any given type, therefore, all samples should act reasonably alike. The assumption of uniform sizes and shapes to explain the probability relationship would seem justified under these conditions.

Mansfield recognizes the importance of the ratio of the distance between nominally adjacent droplets and distortion. A greater amount of distortion would be effective at greater distances, and would therefore touch off a greater number of mergers. It was reasoned that distortion was proportional to temperature gradient, dT/dx, which was then included in equation 6 to represent this factor. It is not clear, therefore, why Mansfield states that this factor is omitted.

The possibility of secondary and tertiary mergers has already been stated in the paper. They have not been specifically included in the formula, but it seems reasonable that they would follow, at least roughly, the over-all probability versus moisture law that governed the original merger. If this is true, the equation accounts for them through an increased constant k.

The distance through which a merged droplet may move can be greater than the width of a droplet, as has been stated before. The distance need not be great in terms of total soil volume, however. The concept of moisture "lost," with which Mansfield has difficulty, is merely net loss within a given area. Some moisture has moved in over the border and more has moved out, but the individual droplets themselves need not have moved relatively long distances.

There is nothing in the paper to contradict Mansfield's comment that surface tension movement must occur quickly. In fact, the tests have so far confirmed this. Since the movement is rapid, the factor M_t should include the moisture received from the adjacent warmer area. Such a complete consideration of M_t would eliminate the uniform distribution of final moisture between parallel plates, to which Mansfield objects in his second paragraph. This factor was included in the analysis of the center points of Smith's data. It was not considered in Neher's analysis, however, since this factor is of less importance in the case of hot pipes and cables, where the volumes of earth increase along the outward lines of heat flow, and since the error in its omission is on the conservative side, indicating more movement than can actually occur. This factor is of particular importance, however, in the case of the heat pump.

Hadley makes the observation that freezing earth around a ground coil may cause the moisture content to exceed the field capacity of the soil. This is undoubtedly the case, since the frozen soil interferes with the natural process of percolation which would otherwise relieve the soil of this excess moisture.

He also makes a very interesting application of equation 6 to actual heat pump data. A great deal remains to be done on this phase of the problem before all that happens in the field is completely explainable. The rigor of Hadley's application could be improved by the inclusion of two effects which tend to cancel in the final answer; the larger volumes between the nonconcentric outer isothermals, and the change of M_t in the inner rings. It is still a good approach to the problem, however, within the limits intended.

High-Pressure Gas-Filled Cable Impregnated with Extra-High-Viscosity Oil

DURING 1941, a 7-mile circuit of 120-kv high-pressure gas-filled pipe-type cable known as the *SMD*-type cable was installed in the system of The Detroit Edison Company. This installation has been in satisfactory operation since it was energized on December 31, 1941, and has been described previously before the Institute.[1]

When this first *SMD*-type cable for commercial service was being contemplated, it was felt that an impregnating compound of much higher viscosity than that normally used in the mass-impregnation process should be employed. At that time, the status of the art was such that preimpregnation of the tapes seemed to be the only method of assuring satisfactory impregnation throughout the wall of insulation. Also, preimpregnation would provide sufficient channels in the insulation to assure ready access of gas to all locations in the insulation wall.

Another line of *SMD*-type cable is being installed now at Detroit, a 12-mile circuit connecting Warren and Northeast stations. When this new line was being contemplated, mass impregnation of the insulation was seriously considered. There were two main problems in conjunction with the question of mass impregnation versus preimpregnation. One was concerned with the question of whether satisfactory impregnation could be achieved by means of the mass-impregnation process, when a heavy wall of insulation was to be impregnated with a highly viscous oil of 3000 Saybolt Universal seconds (6 poises) at 100 degrees centigrade. The other one was whether, in a mass-impregnated cable, a supply of gas could be assured at all locations in the insulation to prevent ionization at operating voltage if, for instance, rapid cooling of the cable should occur, with consequent increase of the viscosity of the impregnant.

Characteristics of Saturant

High-pressure gas-filled cables require for their permanent integrity the retaining of a sufficient amount of their original impregnation to insure against ionization at operating voltage and to maintain satisfactory dielectric strength. Thus, the characteristics of the saturant with respect to their effect on the retention are a prime consideration in the design of high-pressure gas-filled cable.

It is believed that the saturant used in these cables (which will be designated, herein, as *HC-3,000*) is one of the most important elements, resulting not merely in the successful operation to date but in providing the basis for expectation of continued successful operation. For this reason, and because the characteristics of the saturant are so pertinent to the method of manufacture, these characteristics and their significance now will be described in greater detail than previously.

Essentially, viscosity is the important controllable property of the oil that is pertinent to drainage. The relationship between the viscosity of the oil and the changes in the cable caused by drainage has not been fully evaluated because the drainage of the saturant from a cable results from two radically different conditions. One of these has to do with the drainage of the saturant from between the layers and from the butt spaces. The other has to do with the drainage from the substance of the paper itself. Even with an oil such as is used in these cables, having a viscosity of the order of thirty times that of the usual solid-type cable oil, drainage of most of the oil from the spaces between tapes is relatively rapid where there is freedom for the oil to migrate. Drainage from the paper substance because of the very fine capillarity is another matter, and the time required is many times longer.

Comparative drainage of oil from saturated paper as a function of viscosity was studied on compactly-wound rolls of paper. The paper was 5 mils thick and 3/4 inch wide, and had a specific gravity of about 0.9. The rolls were about 2 inches in diameter and weighed about 20 grams. Four such rolls were dried thoroughly under heat and vacuum, and were saturated respectively in four oils having approximately the following Saybolt Universal viscosities at 100 degrees centigrade: 38, 65, 150, and 3,000. The dry weight of the paper was determined prior to saturation.

The impregnated rolls were placed in a horizontal position on blotting paper in an air oven maintained at 80 degrees centigrade. By periodic weighing of the rolls, the amount of oil drained from the rolls was determined, with the results shown in Table I.

It will be noted that the time required to drain 30 per cent of the oil is 100 times as great for the 3,000-second oil as for the 38-second oil, and is seven times as great for the 3,000-second oil as for the 150-second oil. It should be borne in mind that in the samples, drainage has been accelerated greatly over that which would occur in a cable, by the presence of the blotting paper and by the fact that the

Table I. Drainage Characteristics of Saturated Paper Rolls as a Function of Viscosity of Saturant at 80 Degrees Centigrade

Viscosity of Saturant at 100 Degrees Centigrade		Hours Required to Drain Designated Percentage of Original Oil from Sample		
Saybolt Universal Seconds	Poises	Per Cent drainage 10	20	30
38	0.03	3	13	35
70	0.11	10	50	150
150	0.28	20	125	525
3,000	6.0	375	1,725	3,500

Note: Original oil is defined as obtained by extrapolation to zero time from measurements obtained at from 2 to 3½ hours.

vertical position of the oil spaces in the samples as placed in the oven is particularly conducive to drainage.

Consideration was given to various other oils of high viscosity. Reasons for discarding these in favor of the *HC* oil may be listed briefly. Although petrolatum would not migrate at temperatures below its melting point, usually about 50 degrees centigrade, it rapidly becomes fluid as the temperature is increased above that. Thus it is not good from the standpoint of migration, if used at the high temperatures often attained in American practice.

Although petroleum oil with rosin added will give high viscosity, such a mixture generally tends to separate and, moreover, does not produce the very low power factors obtained with the *HC* oil.

A high viscosity could be obtained with a composite consisting of a petroleum oil blended with a suitable plastic. In particular, such a composite can be made with the use of a very high molecular weight isobutylene polymer which, by itself, has the consistency of a sticky plastic solid. However, less assurance concerning ability to obtain initial uniformity and nonseparation thereafter was felt for such a composite than for the *HC* oil.

The constituents of the *HC* oil actually used have a fairly narrow range of molecular weights, and the oil is much more nearly homogeneous with respect to molecular type than are natural petroleum-oil saturants.

Continued experience with the *HC* oil has fully justified its original selection. This oil is produced by polymerization of refined low-molecular-weight olefinic gases. Following are listed some of its properties:

1. The viscosity at 100 degrees centigrade is about 3,000 Saybolt Universal seconds (6 poises), or about 30 times that of the higher viscosity petroleum oils most widely used for cable saturants. The viscosity at 40 degrees centigrade is about 250 poises. This characteristic is shown in Figure 1, together with that of a petroleum oil used widely for saturating solid-type cable.[9]

2. Although the viscosity is very high at high temperature, it is not so great as to prevent cable installation at the lowest temperature considered normal in American practice. Bending of the cable, or installation, presents no problem at −10 degrees centigrade.

3. The electrical properties are such that the oil contributes a negligible amount to the cable dielectric loss.

4. The resistance of this oil to the effects of electronic bombardment, such as occurs during ionization in a cable, is considerably more favorable than for petroleum oils.

One of the oustanding characteristics of the oil used for these cables and of the cables themselves is the low initial value of the dielectric loss and the stability with which this is maintained. Laboratory tests on sealed cable samples, maintained at 100 degrees centigrade and extending over more than 7 years, have shown the initial power factor of less than 1/2 per cent to have been maintained without increase. Similar data are reported later herein, showing no change in power factor of installed cables subjected both to high temperature and high voltage.

The inherently low dielectric loss of the *HC* oil does not result purely from the high viscosity but also from the low ion content. When an oil having high ion content, and having a low loss purely because of high viscosity, is blended with a fluid oil, the resultant mixture will have a high power factor. However, the *HC* oil used for these cables has an inherently very low ionic content, as evidenced by the fact that, even when it is mixed with a very fluid oil, the resultant power factor still remains very low.

The combination of low ion content and high viscosity plays a large part in the high stability of the cable made with this oil. For example, this oil, as opposed to one having a high ion content, is not subject to differential sorption by the paper, with the result that it has a power factor higher than would be explainable on the basis of simple saturation. The high viscosity of the oil will minimize power factor increases occasioned by contamination or even by changes within the oil itself.

Dielectric strength of the oil need be mentioned only in passing. This is considerably higher than for more fluid oils. It is not considered, however, that this high strength is particularly significant, nor that it makes any material direct contribution to the performance of the cable.

The *HC* oil is inherently of exceedingly low sulphur content, much lower than for natural petroleum oils, because of its production from low-molecular-weight gases which can be, and are, thoroughly freed from sulphur compounds. The process of producing it does raise a question of the possibility of a small content of organically-bound chlorine. An experimental lot of cable was produced with oil containing 0.03 to 0.04 per cent of chlorine and has been tested extensively. Rather extensive aging tests of paper impregnated with oil having a chlorine content of the order of 0.04 per cent have been made in comparison with control tests on similar paper with various oils of low chlorine content; these comparisons have shown no difference in the aging characteristics. All of the oil which has been used for the commercial production of the 1948 cable has a chlorine content of less than 0.01 per cent.

Typical data showing lack of influence of chlorine content of the saturant on the aging characteristics of saturated paper are given in Table II.

Preimpregnation and Mass Impregnation

At the time of the manufacture of the 1941 cable, it was not considered practical to impregnate this cable by means of the conventional methods involving mass impregnation, and the cable was made with preimpregnated tape, as stated in the beginning of this paper.

Preimpregnation

One satisfactory method of preimpregnation which has been used abroad is a continuous process in which rolls of paper are passed through oil of sufficiently high

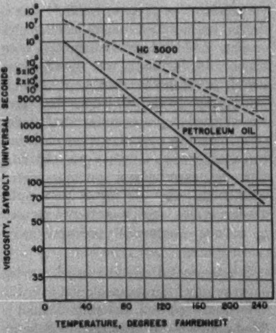

Figure 1. Comparison of the viscosity-temperature characteristics of *HC-3000* oil and a petroleum oil used widely in solid-type cables

temperature and for sufficiently long time. It then may be slit and wound into pads. In an alternate method, used in this country in the manufacture of the 1941 and 1948 preimpregnated cables, the pads of paper are heated and dried under vacuum and then impregnated in a manner similar to the impregnation of solid-type cables. With this latter method of impregnation, the oil readily reaches both faces of every portion of the tape by penetration through the space between tapes, as contrasted to the long and devious path the oil must follow in mass impregnation.

Application of preimpregnated tape presents two main problems. One of these is a simple mechanical one caused by the tendency of the sticky compound to get everywhere it is not wanted—on the taping machine and on the operator's hands and clothing. The only requirement resulting from the stickiness of the compound is that the taping machine must be so designed or so operated that the stickiness of the saturant shall not prevent the tapes from being applied in proper position and with suitable tension. In the manufacture of the 1941 cable, the difficulty was solved by a reduction in taping speed and by the use of additional manufacturing refinements.

The other problem is concerned with the humidity of the surrounding air and the tendency of the treated paper to reabsorb moisture. It has been found that control of the atmospheric moisture to values comparable with that of indoor air in the driest of winter weather (maximum of around 20 per cent) will bring down the rate of reabsorption to a point where no significant change in the properties of the paper takes place during the taping operation. The effective result of this is shown by so-called radial power-factor graphs, of which a great many have been made. In Figure 2 are shown three radial power-factor graphs, *A* and *B* being respectively of commercial preimpregnated cable manufactured under strict humidity control, and of mass impregnated cable. Graph *C* was obtained with an experimental preimpregnated cable made before the installation of the air-drying unit which was afterwards used in making commercial preimpregnated cable.

If a segmental strand is used, having paper or other fibrous insulation over the individual segments, the entire strand is dried and oiled, so that there will be no moisture to migrate from the insulation on the segments to the high-voltage insulation during the course of operation. This treatment also adds to the resistance between individual strands and results in an improvement of a-c resistance of the complete conductor, as compared with its resistance before treatment. Because of the effect upon the a-c resistance, the strand may be given such treatment for this purpose even though it may have no insulating materials which require drying. The shielding tapes over the strand, the preimpregnated insulating tapes, and the shielding and protective coverings are applied in a single machine operation. The coverings over the insulation include two metalized-paper shielding tapes, intercalated; one copper tape intercalated with polyethylene tape; an additional copper tape intercalated with polyethylene tape, and two copper D-shaped skid wires, applied open spiral. The coverings serve several purposes. They constitute an electrostatic shield. They furnish moisture protection to the insulation during handling and until installation of the cable. (They are supplemented in this function during shipment by a special weather-tight reel.) Finally, they act as a bedding for the skid wires.

Mass Impregnation

Various special manufacturing requirements for the use of preimpregnated tape indicated the desirability of reconsidering the possible use of the more conventional mass impregnation. A careful investigation disclosed that, with practical modifications of conventional methods, this would be entirely feasible.

Essentially this meant drying and impregnating at a temperature within the maximum range used for solid-type cable, but keeping the entire length at approximately this temperature. This contrasted with the considerable range of temperature which is permissible with solid-type cable. For solid-type cables, electrical drying had been used extensively for many years, but the choice between electrical heating and steam heating was essentially a matter of economics. In order to obtain the required uniformity of temperature for the mass impregnation with the high viscosity oil, electrical heating for drying became a requirement for long commercial lengths. With that, and with the use of pressure on the oil during the impregnation, complete impregnation could be assured with no longer exposure of the paper to high temperature than with previous good practice. Actual assurance of the impregnation of individual reels was facilitated by measurements of capacitance.

Contrary to the practice with solid-type cable, the oil was pumped from the tanks on the completion of impregnation while the cables were at high temperature. The resultant relative incompleteness of impregnation, about 7 per cent, caused by the contraction of the oil in cooling, leaves space in the insulation through which the gas may reach the entire mass of insulation. It also furnishes some reservoir of gas within the insulation body.

When it once was determined that satisfactory impregnation could be accomplished, the procedure for taping was carried through in a manner entirely normal for solid-type or low-oil-pressure cable. The metalized-paper shielding tapes were applied along with the paper insulation, but the copper tapes intercalated with the polyethylene tapes, and the D-shaped skid wires were applied subsequent to impregnation.

The mass-impregnated cable contains, at the time of manufacture, a greater amount of free oil in the butt spaces than does the preimpregnated. This results in a somewhat higher dielectric strength and a higher voltage at which ionization begins. Since, however, this difference cannot be considered permanent, it is accepted that this difference in dielectric strength may not be significant of long-time difference in performance.

The surge strength of the mass-impregnated cable has been found to exceed slightly the values previously reported for the preimpregnated type,[1] which are among the highest values published for any type of insulation.

On the mass-impregnated cable, dielectric loss values have been slightly

more uniform than on the commercial preimpregnated cable made in 1941. However, there is no significant difference observable in this respect between the mass-impregnated cable and the preimpregnated cable made in 1948.

Effect of Sudden Temperature Changes on the Electrical Performance of the Cable

It has been pointed out that satisfactory impregnation can be achieved by means of the mass-impregnation process even when a 600-mil wall of paper insulation is to be impregnated with an oil of a viscosity of 3,000 Saybolt Universal seconds at 100 degrees centigrade. Another question in connection with the use of such high-viscosity oil in the mass impregnation of high-pressure gas-filled cable, is one pertaining to the electrical performance of such cable in service operation.

Specifically, this question is concerned with the action of the very viscous oil when a heavy load on the cable is reduced suddenly to an extremely small load, especially during the winter season. This sudden and major reduction of load will result in a rapid cooling of the cable, with consequent rapid increase in the viscosity of the impregnating oil and decrease of the volume occupied by it. This contraction of the oil will result in enlarged void spaces; this condition, coupled with the possibility that the increased viscosity of the oil might result in the blocking of gas passages, might be thought to lead to the formation of low-pressure regions within the insulation of the cable. This mechanism might lower the gas pressure in the voids so much that the ionization-starting potential would be reduced to a dangerous value, and ionization might occur in the cable at operating voltage. It was pointed out, however, that two effects combine to prevent dangerous lowering of gas pressure. First, in the mass-impregnated cable, the gas spaces occupy a very significant volume, so that only a minor decrease in gas pressure may result from shrinkage of the oil. Second, the low-gas-pressure regions receive gas that has been sorbed by the oil at the higher pressure and is released by the oil upon pressure reduction in the adjacent gas spaces.

In order to obtain direct information concerning the effect of sudden temperature decreases on the ionization-starting potential, a series of tests was conducted.

Tests to Determine the Effect of Sudden Temperature Drops on the Ionization Starting Potential

After completion of a series of exploratory tests, a program was worked out for experimental study that included tests on samples of mass-impregnated cable and, for purposes of comparison, on samples of preimpregnated cable. It was expected that, in the case of preimpregnated cable, the relative freedom from oil of the butt spaces would largely eliminate the possibility that sudden decreases in temperature of such cables would produce low-pressure regions. Information concerning ionization-starting potential, obtained with preimpregnated cable under various conditions, would serve, therefore, as an excellent basis for comparison in determining the effect of mass impregnation on the ionization-starting potential under essentially identical conditions. For this purpose, tests were conducted on 600,000-circular-mil preimpregnated and mass-impregnated cable having an insulation thickness of 600 mils.

The test procedure was developed with the intention of reproducing important temperature variations to which a commercial cable installation or definite parts of it might be subjected during both normal and extreme conditions of service operations. In an attempt to cover the temperature variations that seemed most important from an operating point of view, the test procedure was arranged to include three successive tests.

In each of these three tests, the ionization-starting potentials were determined at significant periods by means of power factor–voltage measurements. The same test samples were subsequently employed in the study of the effect of sudden gas-pressure releases on both the a-c breakdown strength and the ionization-starting potential of this cable. This phase of the general study is reported in the next section of this paper.

One test was designed to simulate conditions that might exist for the buried-pipe installation during the summer season, when the ground temperature at the pipe level is at the maximum for the year, the cable is heavily loaded, the temperature conditions are at equilibrium, and the load is suddenly reduced to zero with the cable remaining energized.

A second test was to simulate conditions that might exist for the buried-pipe installation in the winter season, when the ground temperature at the pipe level is at the minimum, and other conditions are essentially the same as in the first test.

The third test to determine the effect of sudden temperature drops on the ionization-starting potential was concerned with conditions that might exist in connection with the cable in the vertical riser pipes at the terminals in the winter season when extremely low air temperatures prevail.

Test Procedure

Some of the details of the test procedure may be of interest. Each 33-foot length of test cable was covered, over the *D*-wire, with a heavy lead sheath which was reinforced with cotton and metal tapes to withstand the internal gas pressures to be used. The sheath was removed from the ends to permit application of the terminals. To prevent gas from entering the insulation by way of the ends, special copper lugs were provided which were attached to the conductor and were sealed to the adjoining part of the insulation by a long, tapered, taped joint. Added insulation was applied over the factory insulation, and 5-foot phenolic stop tubes with metal ends, similar to the stop tubes used in the service terminals, were employed to complete the pressure-tight gas container. One metal end of each phenolic stop tube was sealed to the conductor, and the other metal end to the sheath with its reinforcement, at both ends of the cable. The cable then was placed horizontally on tall wooden horses, with the cable ends sloping downward. Over the stop tubes were placed laboratory-type condenser terminals. To restrict still further any entrance of gas from the ends and to aid in the insulation of the terminals, high-viscosity oil was used to fill any remaining spaces within the stop tubes. Gas pressure then was built up as desired, and was maintained for several hours before a new stage of the test was begun.

Current for heating the conductor was provided by a transformer, the secondary of which was insulated from the primary and core to withstand the applied test voltages of up to 200 kv. Provision was made for determining the mean temperature of the conductor by measuring its resistance. This was done with a Kelvin bridge which could be switched on quickly after removal of the high voltage and high current. Sheath temperatures were determined by thermocouples soldered to it.

After determining the current–temperature characteristics of the cable, sufficient current was passed through the conductor to stabilize the temperature at the desired value. While current was flowing, measurements were made of power factor at different voltages up to 200 kv. With these completed, and with the dielectric-loss bridge in balance, the current was interrupted and the bridge promptly rebalanced. Comparison of the measurements made before and immediately after current interruption serves, incidentally, to determine the small error in the power factor indication as a result of the current flow. The chief value of the measurements before current interruption is, however, that they serve as a rehearsal of the measuring technique, to expedite the subsequent measurements and to increase their reliability. During the cooling of the cable following the interruption of current, power-factor measurements were made in series of tests in rapid succession.

In order to simulate the rate of cooling which might occur during extremely cold winter weather following removal of the maximum load that could be carried under such a condition, special provisions were made to cool the sheath. Four lead pipes about 1 inch in diameter were flattened and laid as elements against the reinforced sheath, equally spaced around the circumference. Provision was made to circulate cold brine through these, two pipes in parallel carrying the brine in one direction, with return through the other two. The brine was chilled by dry ice. The temperature was controlled by the rate at which dry ice was added.

Test Results and Conclusions

Prior to the heating and sudden cooling of the test samples, some information was obtained regarding the ionization-starting potentials at room temperature when various gas pressures are employed for various lengths of time. Representative results obtained with preimpregnated cable, as well as with mass-impregnated cable, are given in Table III.

It should be pointed out that these results refer to cables that had not been subjected to gas-pressure cycles before the values of ionization-starting potentials were obtained. When ionization-starting-potential determinations are made at room temperature and various pressures, on cables that have previously been subjected to gas-pressure cycles, then the values obtained will depend on the history of the cable, as is shown in the section dealing with the effect of sudden, repeated gas-pressure releases.

From the mass of information obtained during the three tests outlined previously, only those results will be considered that have a direct bearing on the ionization-starting potentials that prevail during the cooling periods of the three different heat cycles under consideration.

Test I. Pertinent results that were obtained during the test designed to simulate conditions that might exist in buried parts of the cable installation during the period of the year when ground temperatures are highest, are shown in Figure 3 for both the preimpregnated and the mass-impregnated cable samples. For the experimental determination of the ionization-starting potentials that prevail during such conditions, the cable samples involved in this test were heated by means of conductor circulating current until a conductor temperature of 100 degrees centigrade was reached. This temperature then was maintained until equilibrium of the system had been assured. With the cable assembly suspended in free air at the room temperature of approximately 25 degrees centigrade, all the load was dropped suddenly, and the cable was allowed to cool to room temperature. It should be noted that the preimpregnated cable was subjected to a nitrogen gas pressure of 200 pounds per square inch gauge, whereas the mass-impregnated cable sample was subjected to a nitrogen gas pressure of only 136 pounds per square inch gauge during the determination of the ionization-starting potentials. The mass-impregnated cable was therefore subjected to more unfavorable test conditions. The reason for the use of this lower gas pressure was that, at a pressure of 200 pounds per square inch gauge, the ionization-starting potentials were found to be above 200 kv during an exploratory test which was conducted previously on another specimen.

† Average of two determinations

In this graphical presentation, the ionization-starting potential is given as a function of time elapsed since the sudden termination of the heating of the cable. In order to enable correlation of the respective values with the temperatures prevailing at the conductor, the conductor temperature also is given as a function of cooling time. Only one temperature curve is given for both cables inasmuch as

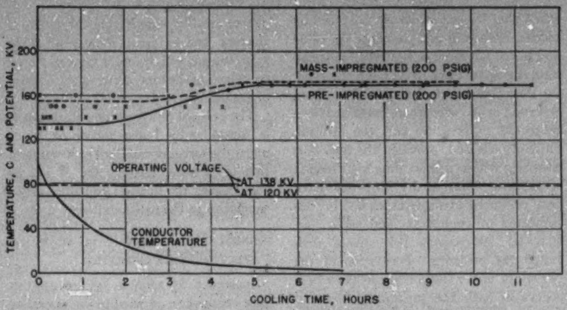

Figure 4. Comparison of ionization-starting potentials existing in mass-impregnated and preimpregnated cables during the cooling period of Test II

there was little difference in the temperature–time relations of the two cable types.

It can be seen that in some instances the measured values of the ionization-starting potentials show a considerable spread with respect to the curves plotted. It is nevertheless apparent that the curve drawn for the mass-impregnated sample indicates the true tendency of change in ionization-starting potential with respect to cooling time. Values of ionization-starting potential for the preimpregnated cable sample were determined only during the first 2¼ hours of the cooling period, but tests reported later herein leave no doubt that the character of the complete curve would be similar to that of the one given for the mass-impregnated sample.

It is concluded from the results obtained that no dangerous drop in ionization-starting potential is experienced when, with an ambient temperature of 25 degrees centigrade, the temperature of the insulation falls to ambient from that which exists when the conductor is at approximately 100 degrees centigrade. In order to indicate graphically how much the ionization-starting potentials are above the potentials that exist across the insulation during service conditions, these potentials are indicated in the graph for 3-phase operating voltages ranging from 120 kv to 138 kv. It should be noted that, for the properties of the thermal system involved, the "sudden" drop from a conductor temperature of 100 degrees centigrade to the ambient of approximately 25 degrees centigrade involved an interval of several hours.

Test II. The results of this test, which was to simulate conditions that might exist for the buried-pipe installation when the ground temperature at the pipe level is at the minimum, are shown in Figure 4. This test, in which the load was reduced suddenly to zero when the cable temperatures were stabilized with the cable suspended in free air at 25 degrees centigrade and a conductor temperature of 100 degrees centigrade, and in which a refrigerant at zero degrees centigrade was applied simultaneously with the removal of the load, was employed several times with each of the cable samples. During the repetitions of this test, gas pressures of nominally 150 pounds per square inch gauge were applied in some cases, and of 200 pounds per square inch gauge in others. In order to keep the presentation of the results as simple as possible, only the results obtained in one cooling period with a pressure of 200 pounds per square inch gauge are shown for each of the two types of cable.

From the results obtained in this test, the conclusion again is that no reduction in ionization-starting potential results from a sudden drop of cable temperatures, even though more severe test conditions are employed than in the case of Test I.

Test III. Ionization-starting potentials that were determined on the specimens of preimpregnated and mass-impregnated cables used in Tests I and II are shown in Figure 5 for the conditions that might exist in vertical risers when extremely low air temperatures prevail. In this test, the load current, which had produced stabilized conditions with the conductor temperature at approximately 50 degrees centigrade while a coolant at −20 degrees centigrade was being circulated around the outside of the cable, was reduced suddenly to zero. It is in this test that the first definite indication appears of a decrease in the ionization-starting potential as a consequence of rapid cooling of the cable. It also should be noted that only the mass-impregnated cable shows this drop.

From a study of these results, it is concluded that, although a definite drop of ionization-starting potential is found in the case of mass-impregnated cable, the minimum ionization-starting potential is still safely above potentials that occur during normal service operation (approximately 65 per cent above that for 138-kv operation). Also, attention should be called to the fact that even this small reduction of ionization-starting potential existed only for a brief period, beginning shortly after the removal of the load current and lasting until little more than one hour had elapsed after removal.

Conclusions

In connection with the observed spread of ionization-starting-potential values, a few words regarding the manner in which these values were determined may be in order. During the series of power factor–voltage determinations, the voltage usually was changed in 10-kv steps. Each power factor–voltage characteristic was plotted, and, from these smooth curves, the potential point was determined at which the curve deviated from a straight line.

In many cases, the change in power factor was so gradual that the ionization-starting potential could be determined only with an uncertainty amounting to ±5 kv, and in some cases an even greater uncertainty existed, particularly since the power-factor values were determined usually to within only 0.01 per cent.

The shape of the curves showing the change in ionization-starting potential with progressive cooling of the cable is of particular interest. It should be pointed out first that the gas pressure in the space surrounding the cable proper always was maintained essentially constant during the cooling period, that is, gas was allowed to flow into this space from a nitrogen tank in accordance with the requirements resulting from progressive cooling. Next, it should be recalled that, with respect to ionization-starting potentials, it is not only the absolute gas pressure that is of importance, even though in practical applications the gas pressure is taken as the criterion of prevention of ionization. When the chances for ionization to occur are judged only on the basis of changes in pressure in a given system, this can be done accurately only if constant temperature conditions prevail. When different temperature conditions are involved, however, as in this series of tests, then it is no longer the absolute pressure that is of importance, but it is the density of the gas which must serve as a basis for comparison.

From these considerations it is apparent that, if the absolute gas pressure is maintained at a constant value during the cooling period, not only in the gas space surrounding the cable but also within the voids of the cable insulation, an increase in the ionization-starting potentials must result with progressive cooling. Inasmuch as the gas pressure around the cable was maintained at a constant value during the cooling period, and inasmuch as in general the observed ionization potentials in these three tests did increase with progressive cooling, there can be little doubt that the gas supply had essentially free access to practically all the voids in the insulation.

If the inflow of gas with progressive cooling always had been sufficient to maintain constant pressure in all of the voids, and if there had been no dimensional changes in the voids occurring simultaneously with the progressive cooling, the increase in ionization-starting potentials would have progressed in strict conformity with the decrease in temperature. The observed characteristics of an *S*-shaped curve indicate, therefore, that dimensional changes of the void structure, or some other undetermined mechanism, did operate in such manner as to prevent complete conformity of increase in ionization-starting potentials, with concurrent decrease in temperature during the early part of the cooling periods. Whatever the responsible mechanism, it remains quite evident that even during the early part of the cooling periods, reductions in ionization-starting potentials were of minor importance.

Effect of Sudden, Repeated Gas-Pressure Releases

During the dissection of cable from an experimental installation of 120-kv high-pressure gas-filled cable of the preimpregnated type, a peculiar condition was noted which had the appearance of "dry" spots in the individual tapes of the oil-impregnated paper insulation. These dry spots were generally of small diameter and appeared in clusters, in the aggregate giving the paper surface a "peppered" appearance. When viewed by reflected light, the spots appeared lighter than the unaffected portions of the paper; when viewed with transmitted light, the spots appeared darker. Microscopic examination gave evidence of the presence of clusters of gas bubbles within the paper tapes at the dry spots.

Subsequent investigation has established that the dry spots are produced by sudden release of gas pressure. In cable which had not been subjected to gas pressure, dry spots have never been observed. On the other hand, dry spots have been observed in all cases where cable had been subjected to pressure and the pressure suddenly released, provided the cable was dissected within a short time after release of pressure. Similar dry spots also have been produced in single tapes and in rolls subjected to application and sudden release of 200-pounds per square inch gauge gas pressure. Formation of the dry spots, under the conditions described, occurs in both the preimpregnated and mass-impregnated types of cable. It also has been produced in the laboratory in tapes saturated with low-viscosity oil, so that the condition is not peculiar to the high-viscosity oil used in the cables here discussed.

Dissection of cable samples also has established that the dry spots may persist for many weeks after release of pressure, but that they become less prominent as time goes on. The dry spots disappear much more rapidly if the pressure is reapplied.

The formation of these dry spots can be explained in the following manner. When, after installation of the cable in the pipe, the gas pressure in the pipe is increased, the weight or amount of the gas sorbed in the oil will increase in proportion to the pressure, and, when the pressure in the pipe is decreased, the sorbed gas will be decreased in proportion to the pressure. The release of sorbed gas when the pressure is reduced, especially if the pressure reduction occurs at a high rate, is of particular significance with respect to the impregnating compound contained within each tape. The gas that was sorbed cannot readily escape from the inside of the tape, and, in forcing its way out of the tape, the gas will dislocate some of the oil contained in the tape, forming the clusters of gas bubbles or dry spots.

The gradual disappearance of the spots is caused by the redistribution of the oil under the forces of capillarity. Reapplication of pressure hastens the action by compressing the bubbles and thus aiding capillarity in the redistribution.

SIGNIFICANCE OF DRY SPOTS WITH RESPECT TO CABLE OPERATION

Inasmuch as sudden gas-pressure releases cannot be avoided in the operation of high-pressure gas-filled cables, it became important to investigate the significance of such dry spots with respect to cable operation. To determine the effects, the dielectric strength of tapes containing dry spots, and the a-c breakdown strength, the impulse strength, and the ionization-starting potentials of cables that had been subjected to a number of gas-pressure releases were determined.

DIELECTRIC STRENGTH OF TAPES CONTAINING DRY SPOTS

Dielectric-strength tests were performed on tapes removed from a length of unused cable which had been subjected to the following pressure program:

1. 200-pounds per square inch gauge nitrogen pressure for eight hours.
2. Sudden release of pressure to atmospheric.
3. Atmospheric pressure for 16 hours.
4. 200-pounds per square inch gauge nitrogen pressure for eight hours.
5. Sudden release of pressure to atmospheric.

The dielectric strength of tapes with

dry spots, removed 65 hours after the final release of pressure, was found to be 680 volts per mil; 2 weeks–840 volts per mil; 1 month–1,030 volts per mil. These values compare with 1,780 volts per mil on tape taken from a cable specimen which had not been subjected to gas pressure.

From these results it can be seen that there was a considerable decrease in dielectric strength as a result of the presence of dry spots, and that the dielectric strength improved with time elapsed since the last gas-pressure release. These dielectric-strength determinations were made with the tapes under atmospheric pressure, whereas under service conditions the tapes are under a pressure of approximately 200 pounds per square inch gauge. The dielectric strength of the portions of the tape that are well impregnated will be little affected by such an increase in pressure, but the dielectric strength of the clusters of gas bubbles or dry spots will be improved materially if the pressure in the dry spots is increased to 200 pounds per square inch gauge.

It is well to note here that the dielectric strength of the component tapes has only a limited bearing on the dielectric strength of the cable as a whole. The limiting dielectric stress in a cable is determined primarily by the dimensions and distribution of the butt spaces and by the electrical properties of the medium within these spaces, in the present case nitrogen at 200 pounds per square inch gauge. Even the spotty paper, having only about one-half the original dielectric strength of the saturated paper, is stronger electrically than the gas in the butt spaces.

In order to determine the practical significance of dry spots in high-pressure gas-filled cables, a-c breakdown and impulse tests were conducted on cable samples under a gas pressure of approximately 200 pounds per square inch gauge.

Effect of Gas-Pressure Releases on A-C Breakdown Strength

For the a-c breakdown test, two samples of 600,000-circular-mile cable provided with a 600-mil wall of insulation were used. One sample was of the preimpregnated type; the other, of the mass-impregnated type. Approximately ten pressure–release cycles, from 200 pounds per square inch gauge to atmospheric pressure, were applied to each sample immediately before the breakdown tests were started. In the breakdown tests, a voltage of 200 kv was applied for nine minutes; then the voltage was raised in 2-kv steps every nine minutes until 240 kv was reached; then at 8-minute intervals until 264 kv was reached, and then at 7-minute intervals until failure occurred. A nitrogen pressure of 200 pounds per square inch gauge was maintained in the samples during the breakdown tests. Under this treatment, breakdown occurred at 270 kv for the preimpregnated cable, and at 274 kv for the mass-impregnated cable. These breakdown values are in the same range as those of similar cables which had not been subjected to gas-pressure releases. These values cannot be compared properly with those of oil-filled or newly-made solid-type cables. The purposely-drained gas-pressure cables are not as well adapted as are these other types to withstand this particular kind of test. This does not, however, nullify the usefulness of the test for the comparison made.

Effect of Gas-Pressure Releases on Impulse Strength

For the first impulse-strength test, three specimens were used that were cut from a 95-foot length of cable removed from the experimental line. The cable had been in operation for $4^1/_2$ years, and during this time there had been approximately 20 gas-pressure releases. It was found that the impulse strength of these three specimens was somewhat higher than that of two other samples tested at the time of the installation of the experimental cable (640, 730, and 728 kv as against 700 and 500 kv). However, the impulse strength in either case was rather low, and the impulse failures occurred in regions of wide butt spaces. In this connection it should be mentioned that this experimental cable was the first one of this type manufactured and installed in this country. Further, this cable did not include several improvements in construction and uniformity of fabrication embodied in the original commercial line. The impulse-test results, therefore, were not necessarily conclusive with respect to the effect of dry spots on the impulse strength, inasmuch as other effects may have masked the effect of dry spots.

In order to obtain more reliable information concerning the effect of dry spots on the impulse strength of the cable, a specimen of mass-impregnated cable with 600,000-circular-mil conductor and an insulation thickness of 500 mils subsequently was subjected to impulse tests immediately after the cable had been subjected to ten gas-pressure release cycles. During these cycles a nitrogen pressure of 200 pounds per square inch gauge was maintained for approximately eight hours; then the pressure was released suddenly to atmospheric pressure, where it remained for 16 hours. Pressure at 200 pounds per square inch gauge then was applied, and two impulses were made at 680, 780, 860, and 955 kv. Full generator voltage of approximately 1,060

kv then was applied, and the sample failed during the eighth impulse at full generator voltage. Two similar samples of cable, but of the preimpregnated type and not subjected to gas-pressure releases, had been tested previously and had failed at 890 and 960 kv, respectively. It is evident from this that the surge strength of cable that has been subjected to gas-pressure releases is quite satisfactory.

EFFECT OF GAS-PRESSURE RELEASES ON IONIZATION-STARTING POTENTIAL

Another criterion that is of considerable importance in the operation of high-pressure gas-filled cable is the ionization-starting potential as affected by sudden gas-pressure changes. The reason for its importance is twofold: first, it may be used to determine how soon such a cable may be safely energized after pressure is restored subsequent to a pressure release to atmospheric pressure, and second, it may be a guide in determining how long the cable may remain safely energized when the gas pressure in the pipe is essentially lost.

In order to obtain experimental data concerning this criterion, power factor–voltage determinations were made on both the mass-impregnated and the preimpregnated cable specimens during the cycles of gas-pressure changes to which the cable samples were subjected prior to the a-c breakdown tests that have been discussed. The schedule of pressure cycles employed in the series of tests conducted on a sample of mass-impregnated cable is given in Table IV, together with a legend referring to Figure 6, in which a graphical presentation of some of the pertinent test results is given.

Only the results obtained with mass-impregnated cable are given, inasmuch as those obtained with preimpregnated cable are of essentially the same character. All the results given refer to conditions existing at room temperature. These series of gas-pressure changes were applied to the cable specimens that had been subjected to the three tests discussed under the previous section entitled "Effect of Sudden Temperature Changes on the Electrical Performance of the Cable."

From the results plotted in Figure 6, it can be seen that there is a tendency toward an increase in ionization-starting potentials with an increase in the number of gas-pressure applications and releases. Curves 2 and 7 from this figure are replotted in Figure 7, together with essentially corresponding results that were obtained in similar tests made on the preimpregnated-cable specimen. In this figure, potentials across the insulation wall that exist when the cable is in 3-phase operation at 120 kv and at 138 kv are indicated again in order to show the relation of the ionization-starting potentials to the potentials actually existing in normal operation.

It is not inappropriate to refer here to tests carried on for several months on a cable sample, at a voltage above operating voltage and with one end open freely to the atmosphere. The cable for this test was part of that made for the 1941 commercial line. The voltage was raised at a constant rate from 90 kv to 113 kv (compared with the rated voltage to ground of about 80 kv). During 2,800 hours of this time the cable was subjected to daily load cycles to 70 degrees centigrade, one end being open so that during the cyclic loading it could breathe in air. The test finally was discontinued without failure after a total time of 4,400 hours (about six months).

It is shown by ionization measurements made following sudden release of pressure, that the ionization voltage remains above operating voltage for several hours. Similarly, after reapplication of pressure, the ionization voltage rises so quickly above operating voltage that such cables may be energized safely immediately after service pressure is restored subsequent to a pressure release to atmospheric pressure. The long-time test at atmospheric pressure is of related significance in that it shows that even a short period of ionization, should it occur following sudden loss of pressure, does not produce rapid deterioration.

CONCLUSIONS CONCERNING THE EFFECT OF SUDDEN GAS-PRESSURE RELEASES

The results of this study of the cause and significance of dry spots observed in the insulation of high-pressure gas-filled cable lead to the conclusion that dry spots can be expected to appear in high-pressure gas-filled cable when the gas pressure is suddenly released, but that such dry spots apparently have no harmful effect under service conditions. Although these experimental results show no harmful effects even for repeated sudden pressure releases, such severity of conditions is not necessary and is not suggested for commercial installations. In order to insure against significant effects, it is desirable to arrange that sudden releases of pressure be made only at infrequent intervals.

Performance of Both Types of Cable in an Experimental Field Installation

An experimental field installation of pipe-type cable was completed in 1941 in the grounds of Warren Station of The Detroit Edison Company system. The purpose of this installation was to gain experience in the installation and the operation of gas-pressure pipe-type cable, and to procure experimental data concerning its electrical performance and thermal behavior. Much of the information gained with this installation has been published in 1942,[1,3] and in 1948.[4] The latter paper contains detailed information concerning the general layout. It is evident that such an installation lends itself readily to a study of various kinds of pipe-type cable, as well as to a study of the merits of modifications of existing types—for instance, the performance of mass-impregnated *SMD*-type cable as compared with that of preimpregnated *SMD*-type cable, as it was originally designed.

When the desirability of the use of mass-impregnated high-pressure gas-filled cable for the system of The Detroit Edison Company was being considered, two lengths of mass-impregnated cable and one length of preimpregnated cable were installed in one pipe section of approximately 660 feet in length. All three single-conductor cables that were used to make up the 3-phase cable in this pipe section had 600,000-circular-mil conductors, the two mass-impregnated cables having Compack-round conductors with 600-mil and 500-mil insulation, respectively, and the preimpregnated cable having a concentric-round conductor with 600-mil insulation.

This installation has been under test since the early part of August 1947, and has been subjected during that time to severe loading conditions. At first, continuous load was applied for about 180 hours with conductor temperatures at approximately 70 degrees centigrade, followed by 140 hours at 80 degrees centigrade, 145 hours at 90 degrees centigrade, and 1,475 hours at 100 degrees centigrade.

After continuous load had thus been applied for approximately 1,940 hours, the cable was subjected to daily load cycles of 12-hour heating and 12-hour cooling periods. During these load cycles, currents of sufficient magnitude were circulated to bring about a conductor temperature of approximately 100 degrees centigrade. To date these cables have been subjected to 310 such heat cycles. A potential of 120 kv, 3-phase, was applied to the cable during all loading schedules.

Power factor measurements were made initially and at various times during the load tests. The values shown in Table V are representative of the results obtained at operating voltage and indicate that little change has occurred in the insulation during the test.

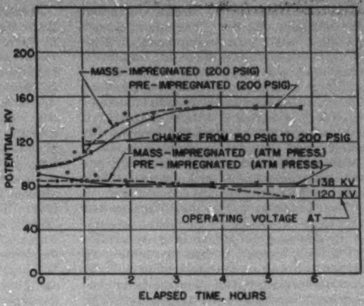

Figure 7. Comparison of ionization-starting potentials existing in mass-impregnated and preimpregnated cables at various time intervals after gas-pressure changes were made

Summary

1. The 7-mile circuit of 120-kv high-pressure gas-filled cable installed in 1941 has fulfilled, during seven years of operation, the favorable expectations indicated in an AIEE paper presented in 1942.[1]

2. Several engineering features of high-pressure gas-filled cable, concerning which there has been no previous publication, have been investigated and are described. The results obtained are favorable.

3. It is believed that the characteristics of the high-viscosity saturant used are very significant with respect to the performance which this cable has given and which may be expected from it. Reasons for this are given, and added details of the oil characteristics are shown.

4. Further tests on an experimental field installation are reported. These show favorable results concerning cable operation at high temperature for both the preimpregnated and mass-impregnated types.

5. A new installation of twice the power-carrying capacity and twice the length of the 1941 installation is nearing completion. Half of the cable is made with preimpregnated tapes, and, except for conductor size and for shipment without lead sheath, is substantially the same as that of the 1941 installation. The construction of the other half of the cable involves mass impregnation of the paper with the high-viscosity oil, in a manner generally similar to the impregnation of solid-type cable.

6. The ability of the mass-impregnated cable to meet special loading and other operating conditions has been ascertained by the rigorous tests reported in this paper.

Discussion

Edwin J. Merrell (Phelps Dodge Copper Products Corporation, Yonkers, N. Y.): The following cable ionization data obtained in our laboratory are pertinent to this discussion. The measurements were made on two 50-foot samples of 138-kv cable mass impregnated with 3,000 Saybolt second at 100 degrees centigrade oil. One length was a round cable with taped sheath such as that described in the paper; the other was an oval compression-type cable with a continuous polyethylene sheath. The cables were installed in horizontal brass pipes under 200 pounds per square inch nitrogen, and terminated in condenser terminals, the ends being double guarded. Ionization factor was defined as the difference in room temperature power factors at atmospheric pressure, when measured at 20 volts per mil (11.2 kv to ground) and 143 volts per mil (80 kv to ground, rated voltage). Initial ionization factors were 0.01 per cent for both designs. After approximately 25 daily load cycles under 200 pounds per square inch pressure with the conductors heated by loading current for eight hours each day, from room temperature (about 25 degrees centigrade to between 100 and 105 degrees centigrade, the ionization factors were measured again. After one day at atmospheric pressure the ionization factors for the round and oval construetions respectively were 0.65 and 0.11; after five days, 2.22 and 0.21 per cent. Thus, in the taped sheath cable, oil pumped out on load cycle, leaving voids within the dielectric, thereby showing the ineffectiveness of the high-viscosity oil in preventing radial migration. On the other hand, the continuous sheath prevented loss of impregnant; moreover, the reversible elasticity characteristic of the polyethylene-sheathed compression cable, even with the conductor at 100 to 105 degrees centigrade, minimized gaseous void formation.

G. B. Shanklin (General Electric Company, Schenectady, N. Y.): The high-pressure gas-filled cable with preimpregnated insulation, as described in the paper, duplicates that used previously in Detroit, and is similar in principle to the Beaver-type cable. The characteristics are well understood and reliability in service at 200 pounds nitrogen gas pressure has been proved both in this country and abroad. Accordingly, no comments are required other than to point out the increased cost and manufacturing difficulties represented by this construction.

The gas-filled cable mass-impregnated with extra-high viscosity compound is something new and, as yet, untried in service. To a lesser extent, it also has inherently higher cost and represents a more difficult manufacturing problem than the more conventional designs used generally. The basic question is whether it offers sufficient advantages to overcome these handicaps. Only time and operating experience will fully answer this question. The makers and users deserve a great deal of credit for this contribution to the cable art.

We have been carrying out a systematic laboratory study of the polybutylenes for some years past, comparing them with the natural petroleum oils over the full range of available viscosities. At the higher viscosities, above the range of the natural oils, Vistanex has been added to obtain the desired viscosity in this comparison. Our conclusions have not always been in accord with those presented by the authors. For instance, it is stated that the polybutylene oils resist electronic bombardment from ionization considerably better than natural oils. On the contrary, we have found very definitely that at any given viscosity the natural oils with or without Vistanex are much more resistant to ionization bombardment. In fact, in this respect and in other ways polybutylenes closely resemble saturated highly-refined white oils.

Until some way is found of stabilizing the polybutylenes against ionization effects we would not care to use them in solid-type cable and low-pressure gas-filled cable where incipient ionization is always likely to occur, and where resistance to and a self-healing effect that extinguishes this incipient ionization are very important factors.

In high-pressure gas-filled cable there is a much wider margin between ionization starting voltage and normal operating voltage. This gives some assurance that incipient ionization will never start in service provided a sufficient pressure is maintained uniformly. If incipient ionization does occur it will lead to serious cumulative damage and with this type of oil it is very important to bear this in mind.

The effects outlined are aggravated by the extremely high viscosity of the oil and the relatively high operating pressure of the gas in the voids. According to our test study, extra-high viscosity oils of any type have no self-healing effect against incipient ionization because they cannot move freely in the paper insulation and accordingly are not drawn into the voids by electrostatic attraction. Also, the high energy in the electronic discharge at high pressure tends to aggravate accumulative action. The net result is that for successful operation there must always be a wide margin between ionization starting voltage and normal working voltage.

It might be pointed out that the drainage tests on rolls of impregnated paper as shown in Table I of the paper have no bearing on ionization characteristics in service as affected by compound drainage. The results in Table I as would be expected show a drainage in direct proportion to the viscosity of the impregnant and as the viscosity increases it requires a correspondingly longer time for the same degree of drainage. In a true gas-filled cable, surplus compound is drained off at the beginning and that which remains is held in place by capillary attraction. When voltage is applied, electrostatic attraction also tends to redistribute the compound in a favorable way provided the viscosity is sufficiently low to allow this. We have made many long-time load cycle aging tests with medium and low viscosity impregnants and under severe conditions of drainage. Many of these results have been presented in AIEE papers and will show that ionization characteristics are not affected by drainage as would be indicated by Table I.

The paper describes some interesting tests on gas pressure release and its effects on void formation and ionization characteristics. The conclusions are that gas pressure release within the minimum time limits that could occur in service has no important effect. We have made numerous tests of the same kind with a wide range of impregnant viscosities and would like to confirm this conclusion that such gas pressure release does not permanently affect the cable.

The test procedure on 33-foot lengths of cable as described in the paper is not entirely clear. No drawings are presented giving details of the end seals and the test terminals. From the description, however, it would appear that these lengths were tested strictly as compression cable, and had not been previously charged with gas to full working pressure. In other words, they were not tested as true gas-filled cable, since no gas in solution or otherwise was in the insulation. The pressure was applied externally on the impervious polyethylene sheath and presumably surplus compound had not been drained as it would be in a true gas-filled cable. The net result was a typical hydraulic compressive action, and about all these tests proved was that a round cable responds effectively to such hydraulic compressive action and is equal in this respect to the oval-shaped cable. If my interpretation is incorrect, it would be appreciated if the authors would explain this test in more detail. In service the cable will act as a true gas-filled cable, provided the gas pressure medium can penetrate and fully saturate the cable cross section to full working pressure and over a full length between joints that might be as much as 2,500 feet, or even more. Since the penetration and absorption of gas is not only a function of length but of compound viscosity also, it would appear that it will require an extremely long time for fully saturated and stabilized conditions to be reached.

One thing that puzzles me is how a preimpregnated insulation can perform as a true hydraulic compressive design. Because of the relatively large void spaces in a cable of this kind, it would appear that it could not possibly perform in this way and ionization would not be suppressed until and after the cable cross section is fully gas-saturated to working gas pressure. Perhaps the authors' comments will throw some light on this. Incidentally, the ionization characteristics as a function of pressure in Table III of the paper do not behave as expected in a true gas-filled cable. The plotted curves do not have a typical drop in ionization voltage as pressure increases. Instead, the curves tend to bend upward and the ionization voltage increases faster than the pressure. Even Paschen's law, which we all know is only approximate, is contrary to the unusual shape of these curves. This again indicates a compressive hydraulic action.

The aging tests on this cable at 100 degrees centigrade confirm the fact that, other things being equal, power factor stability under high-temperature aging improves with increase in viscosity of the impregnant. The reason for this is that conducting ions from the impurities released by heat disintegration are immobilized in the viscous material and their presence cannot be indicated by dielectric loss measurements, as it can with a lower viscosity impregnant. It does not mean that impurities cannot be present to an equal degree in both cases and it raises a question of whether dielectric loss measurements are a true criterion of aging under such conditions. It is a well-known fact that cellulose fiber does disintegrate at temperatures above 80 degrees centigrade, regardless of the impregnant.

It would appear that a good deal more work will be necessary before we will know all that is needed to be known about the characteristics of cable with super-high viscosity impregnants. Certainly, however, the results presented in this paper are promising and justify carrying this work to a full conclusion.

E. S. Halfmann (Philadelphia Electric Company, Philadelphia, Pa.): In describing the characteristics of the saturant, the authors make the following statement:

> "Although the viscosity is very high at high temperature, it is not so great as to prevent cable installation at the lowest temperature considered normal in American practice. Bending of the cable, or installation, presents no problem at —10 degrees centigrade."

This statement gives the reader the impression that cable impregnated with 3,000 Saybolt Universal second *HC* oil is capable of withstanding the bending during installation and the requirements of the Association of Edison Illuminating Companies' (AEIC) bend test as well as cable impregnated with a lighter oil. On the contrary, we have found that cable impregnated with 3,000 Saybolt Universal second *HC* oil would not pass a 16-diameter bend test performed at room temperature according to the AEIC specification for oil-filled cable,[1] while cable built by another manufacturer with the same conductor size and same insulation thickness but impregnated with a lighter oil passed a similar bend test performed on a 12-diameter mandrel.

For the purpose of this test the temporary lead sheath was removed from all cable samples. Of the four samples taken from different manufacturing lengths of cable which were mass-impregnated with 3,000 second *HC* oil, one sample was bent around a mandrel 12 times the diameter of the cable measured over the skid wire and three samples were bent around a mandrel 16 times the diameter of the cable measured over the skid wire. The tests were performed by the manufacturer in the presence of the writer, and followed the routine prescribed in the AEIC specification for oil-filled cable. Upon dissection, it was found that the number of torn tapes in each sample exceeded the number permitted by the AEIC specification by one or two tapes.

The manufacturer claims that bend tests on other samples have been performed successfully even at temperatures as low as −10 degrees centigrade. This inconsistency of results is extremely difficult to explain unless the high viscosity impregnant tends to cement adjacent tapes to each other in time. It is possible that the successful tests may have been made on newly impregnated cable and that the tests referred to in the preceding paragraph were made on cable which had been impregnated several weeks or months prior to the tests.

1. Specification for Oil-Filled Cable. Association of Edison Illuminating Companies (New York, N. Y.), fourth edition, June 1945.

Joseph Sticher, G. H. Doan, R. W. Atkinson, Louis Meyerhoff: The successful operation of the high-pressure gas-filled cable system installed in 1941 and of somewhat similar systems abroad, together with the extensive 1948 installations now in operation, has resulted in acceptance of the general system. Thus, the discussions of this paper have been concerned only with economics or engineering details.

Question has been made as to the performance under ionization of this *HC* oil. This is answered by the extensive comparison that has been made of the relative performance in cable under "load cycle aging tests" of the conventional petroleum oil saturant having a viscosity at 100 degrees centigrade of 100 Saybolt Universal seconds and of an *HC* oil of comparable viscosity. Data of some of these tests have been reported in a previous publication.[1] In these tests, the voltage was raised in geometric progression, over a period of weeks, at the rate of $1^3/_4$ per cent per day. The cable saturated with the *HC* oil withstood failure up to a voltage about 15 per cent higher than that at which the petroleum saturated cables failed—and for a correspondingly longer time.

Other data reported in 1940[2] include tests made by Mr. Halperin with similar excellent results on a slightly different load cycle aging test. The low over-all power factor and uniform radial power factor of this cable after the cyclic aging test are outstanding in comparison with the values that were shown by Mr. Halperin in 1939, as then typical for commercial cable. Some of the tests reported in 1940 were cited at that time to illustrate the value of shielding over the conductor, but they serve equally well to show the excellent performance of the saturant.

The results of these tests have now been confirmed by the exceedingly satisfactory service record of many hundreds of miles of cable made during the last nine years with this type of saturant.

We had once accepted the view now stated by Mr. Shanklin that any ionization at the stresses at which high-pressure gas-filled cable operates, would be destructive. Thus we were astonished at the extraordinary ability of this cable to withstand the ionization that occurs when it is tested at atmospheric pressure and at voltages well above the working voltage. Much higher stresses, indeed, than those used by Mr. Shanklin in his tests at a pressure of 12 pounds above atmospheric. Whatever may be the explanation of the "self-healing," the result is shown very convincingly by the long-time test at atmospheric pressure reported in this paper. This cable had 4,400 hours at average stresses varying from 150 to 190 volts per mil, all at atmospheric pressure. During this treatment the 20 volts per mil power factor, both at room temperature and at 70 degrees centigrade, rose gradually from the initial value of about 1/2 per cent to about 3/4 per cent. The ionization continued to decrease during the time that the cable was subjected to heat cycles. At atmospheric pressure and at 150 volts per mil, the power factor at room temperature dropped from 2.8 per cent to 0.9. At 70 degrees centigrade the drop was from 2.3 per cent to 0.9. Examination showed that these test conditions produced extensive wax formation in the butt spaces.

The ends of the cable were freely open to the atmosphere during these tests and free to breathe in and out during the temperature cycles. In view of Mr. Shanklin's comparison of his saturant with that used by the authors, it is very pertinent to contrast the stability of this cable with data reported by Mr. Shanklin. In 1942[3] Mr. Shanklin made pointed reference to the extreme sensitivity of his cables to exposure to oxygen of the air. He did this by reference to his Figure 11 which shows the effects of oxygen absorption during exposure to air for eight hours of the test length before it was sheathed, but otherwise complete. The 80 degrees centigrade, 20 volts per mil power factor of this cable was around 2 per cent for most of the 400-day test. Somewhat similar 20 volts per mil power factor increase is shown by Mr. Shanklin on various other curves. Thus he referred to his Figure 6 as showing typical test results and, on this, the power factor at 80 degrees centigrade and 20 volts per mil reached 2 per cent in two weeks and was at about this value or above for the remainder of the test. While these specific references apply to cable made with the medium viscosity saturant which he prefers, other references in this and his other papers indicate that his results with high-viscosity saturant were certainly no more satisfactory.

Mr. Shanklin's poor results with his polybutene oils may be explained by his description of his oils. Thus, he referred to the poor resistance of his polybutene oils to ionization bombardment and then said "In fact, in this and other ways polybutylenes closely resemble saturated highly-refined white oils." The polybutylene oils we use are not highly saturated, but on the contrary, consist almost wholly of unsaturated molecules. They combine the desirable very low initial power factor possessed by the "white" petroleum oils with the other essential property of cable oils, namely high degree of unsaturation, and this to a far greater degree than any practical natural oil. Mr. Shanklin is evidently talking about another material entirely! The vast difference in results is therefore not surprising.

We are glad to have Mr. Shanklin's confirmation of our tests and conclusions concerning the effect of gas pressure releases.

On the tests in which large loads were applied to the cable and then suddenly released, Mr. Shanklin concludes that the cable was not acting as a gas-saturated cable at all, but that the gas acted externally upon what he calls "the impervious polyethylene sheath" and that the "net result was a typical hydraulic compressive action" and that the tests prove simply "that a round cable responds effectively to such hydraulic compressive action and is equal in this respect to the oval-shaped cable."

There was no "impervious polyethylene sheath." The covering on the mass-impregnated cable consists of two pairs of intercalated copper and polyethylene tapes. This has been described previously[4] along with flow tests showing that these tapes furnish virtually no obstruction to flow into the cable, even of oil. Much less do they obstruct gas flow under pressure although they are adequate to minimize vapor diffusion into the cable. No polyethylene was present, in cable samples with preimpregnated tape, the copper tape being intercalated with a cotton tape. This length was, indeed, part of the original 1941 cable, taken from a stock reel.

The sealing of the ends of the cable was described in the paper and is shown in Figure

1 of this discussion. The mechanical arrangement shown, together with the use of the heavy saturant to fill the space within the inverted stop tubes, insures very thoroughly that the inner layers of the cable insulation cannot be gas filled by way of the ends, but must receive their gas supply through the coverings and insulation only. This diagram is given in response to Mr. Shanklin's request although the remaining emphasis in his discussion is not to question the adequacy of this seal, but to consider that the cable is so well sealed that gas did not get in at all.

Referring to the preimpregnated cable, Mr. Shanklin, in his subsequent discussion, makes a reply to his first conclusion that the cable behaves as if sealed off from the gas. He says "it would appear that it could not possibly perform in this way and ionization would not be suppressed until and after the cable cross-section is fully gas-saturated to working gas pressure." We presume his emphasis is upon the spaces not occupied by oil and that ionization will not be suppressed until these are occupied by compressed gas. With this we are in complete agreement and would point out, moreover, that it applies equally to the mass-impregnated cable. It must be remembered that after saturation of this cable, the oil is removed from the impregnating tank while still at 125 degrees centigrade and that no further oil enters the cable. The shrinkage of the oil to room temperature is about 7 per cent. A realistic conception of the physical characteristics of the paper tapes gives no basis for expecting them to yield by compression enough to fill this 7 per cent void space to a degree that would be required to affect the ionization voltage.

Mr. Shanklin says that "the ionization characteristics as a function of pressure in Table III of the paper do not behave as expected in a true gas-filled cable." The data shown in Table III cannot be used to determine the shape of the pressure-ionization curve because the lower pressures were not maintained to the point of stabilization. In most earlier ionization tests, gas was permitted to enter through the strand. The measurements at atmospheric pressure and at 50 pounds per square inch gauge were significant simply in showing that, even with the strand sealed, a major portion of the effect on ionization which could be expected from the application of 50 pounds per square inch gauge took place during the first half hour. Where the relationship between ionization voltage and pressure is to be determined carefully at pressures near atmospheric, full-pressure equalization may be very time-consuming because, at low pressures, a lack of equalization to the extent of even 5 or 10 pounds per square inch is so large a proportion of the total pressure. Lack of equalization at high pressures tends naturally to fall within the same absolute range (the same differences in pounds per square inch) as at low pressure. Whereas a lack of equalization of 5 or 10 pounds per square inch is very significant at low pressures, it is of no significance at all at, for instance, 200 pounds per square inch gauge.

Altogether, it is rather a fantastic thought, as Mr. Shanklin recognized, that in such cables ionization could be controlled purely by hydraulic compression, particularly that this could occur even at 50 pounds per square inch gauge. The thought could hardly have arisen without his erroneous impression that the cables were covered with an impervious sheath.

It is of interest that Mr. Merrell has succeeded in saturating laboratory lengths of cable, having a thick wall of paper, with high-viscosity oil, to the extent of obtaining at room temperature and atmospheric pressure an "ionization factor" as low as 0.01 per cent. However, as he shows, the mere heating of the cable not having an extruded sheath drives some of the oil out of the insulation and the ionization factor is no longer of the low initial value. In producing our cable we very definitely avoid the apparently complete saturation obtained by Mr. Merrell. We remove the oil from the impregnating tank while it is still at 125 degrees centigrade. Thus, we naturally obtain ionization at relatively low stress at atmospheric pressure as a result of the large shrinkage of the saturant as the cable cools. But this same shrinkage leaves space for the pressure gas to penetrate throughout the insulation and to produce freedom from ionization under practical conditions.

Mr. Merrell considers that his test on the round cable has significance in "showing the ineffectiveness of the high-viscosity oil in preventing radial migration." In this test, the pressure occurring from the expansion of the oil will rise to whatever value is required to force it from the insulation. But the resultant effect is not related in any manner to the performance of a cable which is purposely incompletely filled and in which there is space permitting the expansion of the oil.

If the unsaturated cable cores which Mr. Merrell saturated are comparable to those with which we have worked, and his saturant similar to ours, it must have required no small effort to force enough saturant into them as they cooled, with the saturant increasing in viscosity, to keep the cables filled and of low ionization factor. While this would be possible at high pressure with a laboratory length that could be penetrated from the ends and through the strand, we would not expect it to be practical with a commercial length, even if it were desirable.

What the purpose is of the test on the compression cable is not entirely clear. Mr. Merrell's tests show that the oval shape allows only partial accommodation for the expansion of the saturant, that is, the cable did not return entirely to its original condition after the heat cycles. But, more important than that, no less difficulty would be encountered with the oval cable than with the round in attempting to cause the cable to be completely oil-filled with the high-viscosity saturant at room temperature, for the reasons already stated. Although the fact is often overlooked, a compression cable cannot function as such and cannot have a good electrical performance unless the cable is full of oil under high hydrostatic pressure at all temperatures, even at the lowest operating temperatures.

In view of Mr. Halfmann's comment we repeat, with emphasis, and without qualification, the statement to which he takes exception "In spite of the high viscosity at high temperature, the viscosity is not so great as to prevent cable installation at the lowest temperature considered normal in American practice. Bending of the cable, or installation, presents no problem at −10 degrees centigrade." Mr. Halfmann's remarks would have been in better perspective if he had mentioned the following additional data concerning the tests he describes. In the cables which he examined, most of the tears were confined to the two metallized shielding tapes over the insulation. Only one insulating tape was torn. In view of the fact that metallized-paper tapes are included in the definition of the insulation thickness, the tears in these plus the tears in one insulating tape were held to constitute an excess over the two torn tapes permitted by the specification.

It may be remarked, further, that of course the purchaser accepted the cable and that it is in service. It is pertinent, also, that over 500,000 feet of cable of this general type was made and placed in service during the same year and that the only occasion for discussing this specification clause was this one with Mr. Halfmann.

Tests were made on a large number of specimens of cable of similar sort but made for three different utilities, and it is completely certain that the statement that was quoted and is requoted is entirely correct, and that this applies whether the cable is new or has been stored for a few months, or a few years.

While, except for some miles installed in San Francisco in the recent winter, all of the cable of this sort made in 1948 was installed in mild weather, a considerable amount of commercial cable in 1941 as well as various experimental lengths have been installed, without hesitation on the part of the manufacturer or the utility, in weather even colder than the minus 10 degrees centigrade of the standard specification.

MEMBER AIEE

Synopsis: This paper outlines a method for calculating requirements of the drive for a weaving loom from knowledge of system constants and without the necessity for extensive testing. When electrical testing is performed, the pulsating character of the load must be taken into account in selection of instruments and in interpretation of data. The value of inertia in the successful drive also is discussed.

BECAUSE the load imposed on motors applied to conventional weaving looms is so complex, including many components of differing characteristics, proper application of such motors has required special skills and laborious techniques. Recently, a program of analytical testing directed at developing a simple straightforward method for selection of loom drives was completed. A new line of loom motors was developed and the methods discussed here played a prominent part in the formulation of final specifications. This paper has been prepared for the purpose of presenting a summary of the fundamentals and a discussion of basic mathematical relations evolved.

The Problem

What is desired is a method whereby, given basic physical constants of a loom, it will be possible to determine the characteristics of the proper drive for it. If the mechanical motions in loom operation can be reduced to a few basic mathematical relations built around values of the loom constants, the job to be performed by the drive may be clearly defined. With these mathematical tools at hand, the task of selecting the proper motor should be exceedingly simplified. This is precisely the approach described in this paper.

Ultimately, the drive chosen must conform to the following functional specifications:

1. The drive must have sufficient torque ability to operate the loom even under the extreme conditions exemplified by the high load break-in period and by those installations where supply voltage may be low.

2. Operation of the drive must be such as to impart the proper "feel" to the loom; a characteristic so important to the trained loom-fixer, and to be evaluated by him. The amount of speed variation pick-to-pick and the character and magnitude of loom vibration are factors which determine the feel. This factor has not yet been reduced to quantitative values.

3. The drive must operate on the loom load without overheating.

The Loom

Weaving, the process of interlacing two systems of filaments arranged in right-angle relation, is done on a machine known as a loom. In its earliest form, Figure 1, it consisted of any convenient horizontal beam from which the warp or lengthwise yarns were hung, a bobbin carrying the weft (or filling) or crosswise yarn, and a flat wand whose functions were to separate the warp ends in order that the bobbin might pass between them and to beat the weft into place after each insertion. Stones often were hung as weights at their lower extremities to maintain tension in the warp yarns during the weaving operation. To obtain a plain 1-up—1-down weave, alternate yarns were moved forward by rotation of the wand. The bobbin was handed across from right-to-left in the "shed" thus formed, and the filling yarn thus laid in position was beaten into the fabric. The wand then was withdrawn and reinserted between the ends, this time with the warp yarns which previously lay on the rear side brought forward, and those in front dropped to the rear. Again the bobbin was passed through the shed from left-to-right, and the wand was used to beat it up into the woven section. This process was repeated over and over to produce a web or fabric.

In Figures 2 and 3 the elements of a modern power loom are shown. In Figure 3(A) a modern loom is illustrated. The same basic functions as practiced in primitive weaving are incorporated in this automatic machine. Warp yarns, which here may number 10,000 to 15,000 or more, are many hundreds or thousands of yards long and are wound parallel on a large spool called a "beam." (This term has been carried over from the early loom construction.) This is placed at the rear of the machine, its center shaft set in bearings to permit rotation as the warp ends are paid off. All of those ends are led up over the guide roll (whip roll), divided into two equal-numbered systems, and laid over and under the lease rods. The principal function of the lease rods is to separate the closely-spaced ends, so that the weaver can trace more easily individual ends when tying broken ones. From here, each yarn is fed through its own "heddle," a steel wire with an eye through which the yarn passes in the harness frame. The raising and lowering of the harnesses, and thus the warp yarns, position those yarns above and below each weft thread in the order required to secure the pattern desired in the finished

fabric. In Figure 2 just two harnesses are shown; the requirement for producing a plain 1-up and 1-down weave. With each pick, or flight of the shuttle, one harness is raised and the other lowered. From each harness, the 2-yarn systems converge to enter the fabric, forming a shed. Between the harnesses and the fell (weaving point) of the cloth, the ends run through the slots (dents) formed between closely-spaced vertical flat wires of the reed, Figure 3. A bell-crank driven lever, called the "lay," carries the reed forward to push the weft yarn into the cloth and then back out of the shuttle's path. The woven fabric passes over the "breast beam," around a positively-driven take-up roll, and onto a winder, the cloth roll.

The shuttle, carrying the weft yarn, is propelled across the loom in flight under the impact of a blow from a rapidly moving lever, called the "picker stick." This stick, usually made of hickory wood, is accelerated rapidly by a cam control and suddenly imparts its energy to the metal-nosed shuttle as it strikes it. The shuttle darts across the loom, decelerating to a stop at the far side under the action of a spring-loaded friction drag in the "box."

In the weaving operation, each of the loom elements performs its function in proper sequence, as determined by cams and gearing. The order in which the operations occur are as follows:

1. Harnesses are positioned to raise some warp ends and lower others.
2. The lay, carrying the reed, moves to the back position toward the harnesses. As it approaches the end of its rearward travel, it is decelerated and its direction is then reversed.
3. Struck sharply by the picker stick, the shuttle flies across the loom, trailing the weft yarn behind it, and comes to rest in the box at the far side.
4. Meanwhile, the lay is accelerated forward, and the reed pushes the weft yarn into the fabric.
5. As it nears its frontmost position, the lay must be decelerated and its direction reversed once again.
6. A ratchet on the end of the take-up roll is notched forward by a pawl driven from the lay motion.

The cycle then repeats as the harnesses change position and the next pick is made.

In order to obtain uniformity in the finished product, the warp yarns must be held under tension at all times. A friction brake or other hold-back mechanism is applied to the warp beam to accomplish this.

Often, in order to secure particular patterns in the fabric, such special motions as the leno or jacquard attachments are added to the loom. Also, on some looms, there is furnished a reciprocating pump, Figure 3, whose function is to supply a vacuum to an automatic bobbin-changing mechanism. For purposes of this paper, the effect on load of such auxiliary equipment is not considered since they are not universally encountered.

Protection

If a warp or filling yarn should break, the loom must be stopped to prevent weaving any appreciable length of faulty fabric. Special electric and mechanical detection devices are provided on the loom to signal the occurrence of such a break and cause the clutch to become disengaged.

Occasionally, for any one of several reasons, shuttle speed on a pick may be slower than normal, or the shuttle may even fail to complete its flight. If the shuttle has not boxed by the time the lay swings forward to drive the weft yarn

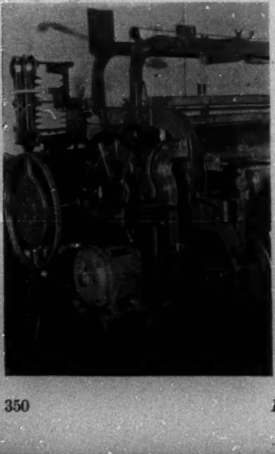

Figure 3A (left). Modern weaving loom

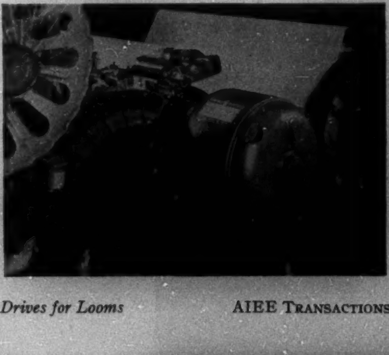

Figure 4 (right). Modern loom motor mounted on loom

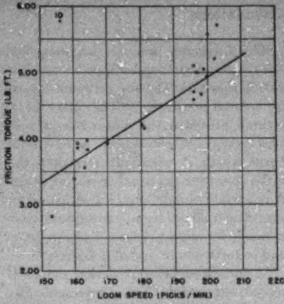

Figure 5. Plot of loom friction torque versus speed (based on 21 tests)

home, there is danger that it will be swept forward by the reed and pushed into the fell of the cloth. Many warp yarns would be broken and irreparable damage would be done to the fabric when the "smash" occurred, necessitating a relatively long shut-down for redrawing the broken warp yarns. To protect against such an occurrence, means are provided for checking on shuttle position to insure that its flight is true and on schedule early in the lay's forward swing. If the shuttle is not on its true course at this time, the "bang-off" protective mechanism operates to simultaneously declutch the motor and position a restraining rod, thus halting the forward travel of the lay. For such a brute-force method of stopping the loom to succeed without causing failure of mechanical elements, the clutch must be disengaged sharply. This occurs at that point in the cycle at which the energy stored in the loom parts is at a maximum.

The Loom Drive

The standard fly-shuttle loom drive consists of a full-voltage starting switch and a single induction motor, Figure 4, whose rating ranges from 1/2 to 2 horsepower and is of either 4- or 6-pole design. To protect against the possibility that the motors may become plugged with lint from the weave shed atmosphere, they are of totally enclosed construction. The sleeve-type, wool-yarn-packed bearing, which has proved successful over the years in loom motor applications, is standard today. The breakdown torque of the loom motor is approximately twice that of the general-purpose motor. The axial length of the motor is kept at a minimum so that it does not influence maximum over-all floor area.

The motor is coupled to the machine through a spur-gear reduction and a clutch. Starting and stopping the loom is accomplished by operation of the clutch mechanism, the motor being permitted to run continuously.

Loom Load

The load imposed on the motor by the various parts of the loom can be studied best by considering the energy required to drive each element individually. Since some of the parts have widely varying velocities, it is better to consider them on a torque basis and to refer the torques to the motor shaft. The more important components of the total load are:

1. Torque to overcome friction.
2. Torque to drive the lay.
3. Torque to drive the shuttle.
4. Torque to actuate the harnesses.
5. Torque to drive the air pump (if included).
6. Torque to actuate a leno motion or jacquard head (if any).
7. Torque to actuate many small devices, such as cloth beam, dobby (harness motion control), and so forth.

For analysis, one pick is considered as one cycle with zero degrees of the crank shaft taken at front dead center of the lay and with 180 degrees at back dead center.

The friction of the loom consists of the actual friction of all bearings, cams, and sliding contacts, and also the constant portion of the unrecoverable part of the energy that goes into driving each part. Friction is assumed constant for purposes of analysis, but in practice it varies widely in a relatively short time with changes in lubrication of the various bearings. Figure 5 is a plot of friction torque versus speed derived from 21 tests on a loom of one size and make. Although this machine was well run in and had expert attention while being tested, friction load varied at each speed considerably. Test 10 shows abnormally high friction preceding a bearing seizure, and, at the time of the test, no distress was noted. The high friction did not show up until the test results were analyzed.

Figure 6 shows, in graphic form, the torque required to drive each of the various loom parts. The torque is plotted against lay position and this also roughly represents time.

Friction is considered ideally constant and is represented by a horizontal line "A".

The lay is a heavy mass oscillating about its center, and requires considerable torque to accelerate and decelerate it. There are two accelerations and decelerations per pick, and so the frequency of the torque is twice that of the pickage, curve "B" Figure 6. During the deceleration, the energy can be recovered and returned to the system either as electric energy or as kinetic energy stored in the effective moment of inertia of the loom. The torque is thus a curve with equal areas above and below the zero line and is a sinusoid as a first approximation. The short connecting rods and the angularity of these rods introduce some harmonics which are not important as far as the motor is concerned, although they may be of considerable interest to the loom designer.

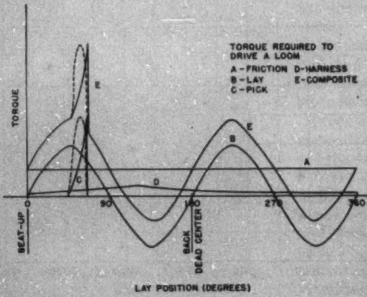

Figure 6 left). An analysis of the nature of components comprising the loom load

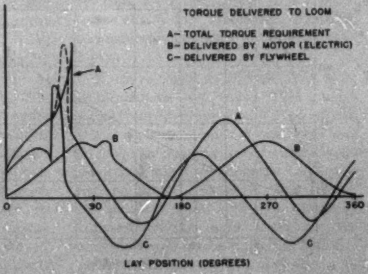
Figure 7 (right). An analysis of the manner in which energy is drawn from motor and rotating parts to drive a loom over its cycle



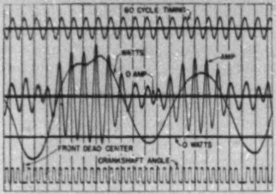


Figure 8. Oscillogram taken in loom test

The shuttle is struck by the picker stick, which in turn is struck by a cam with a very steep rise. This gives the picker stick its high acceleration and demands a sharp peak of torque from the drive system. The shape of the cam, adjustment of linkages, firmness of springs in the shuttle box, and probably several lesser factors affect the configuration and amplitude of the torque curve. The curve of Figure 6 labelled "C" is believed to be a fair representation of the actual values, but it can be approximated for purposes of calculation by a single loop of an eighth harmonic sine wave, as shown in dotted lines.

The torque required to actuate the harnesses, curve "D" Figure 6, is in most cases not great; its average value is included in the friction component. Unless the loom is fitted with a large number of harness frames and is weaving a complicated pattern that requires the lifting of nearly all of them at once, the variations in torque can be neglected. The load represented by the cloth-beam drive, dobby motions, and other lesser elements similarly may be regarded as constant and as a part of the friction factor.

The torque necessary to drive the loom is the summation of these components and is represented by the curve "E" of Figure 6.

This torque is supplied from two sources; the motor, and the inertia or flywheel effect of the revolving and oscillating parts of the system. The latter consists of the moment of inertia of the motor, of the revolving parts of the loom, and of the lay. The load at every instant is divided between the motor electrical torque, and energy from the rotating parts in varying proportions, depending on the motor speed–torque characteristics and the amount of system inertia.

For example, if the loom were driven by an infinitely-large synchronous motor, all the torque would be supplied electrically from the power line. The opposite extreme may be represented by a loom equipped with a large flywheel just after the motor has been disconnected from the line. In this case the flywheel would supply all of the torque. The actual case, of course, is a compromise between these two conditions, and the load is divided between the two sources in varying degree, as is illustrated in Figure 7.

Figure 8 is a tracing of an oscillogram of the current and watt input to a motor driving a loom. The similarity between the shape of the measured motor-input curve and that of the calculated total-load curve of Figure 7 is apparent.

Calculations

The foregoing analysis suggests that the motor output can be approximated by calculation provided the components can be treated additively. They may be so treated provided the motor operates on that portion of the motor speed–torque curve which is essentially straight; this is the case over the usual operating range. A relatively simple loom is considered for purpose of illustration; additional components for pump, heavy harness, leno, and so forth can be added if desired.

As indicated before, friction torque is considered constant and is represented by curve "A" of Figure 6.

The torque to drive the lay is treated as a sine wave with a frequency of twice the number of picks and is represented by

$$B \sin \frac{(4\pi P)}{60} t$$

where

B = peak accelerating torque
P = picks per minute

The variations in the harness torque are neglected, but the average of the torque wave is included in the friction torque A.

The torque to produce the pick is assumed to be a single positive loop of an eighth harmonic starting at the peak of the torque wave of the lay. The energy under this wave is made equal to the

kinetic energy of the shuttle as it leaves the box, and the maximum value is represented by B'.

Motor torque can be approximated over the useful operating range by CS where S is the slip of the motor at any instant and C is the ratio of rated torque to rated slip.

The torque delivered by the flywheel is $I\ dS/dt$, where I is a function of Wk^2 and dS/dt is the acceleration of the flywheel.

These components of torques are equated and the differential equation reduced to the following.

$$T_{max}=A+\frac{B}{\sqrt{1+\left(\dfrac{PWK^2N_0^2S_{FL}}{7.75\ 10^6R}\right)^2}}+$$

$$\frac{B'}{\sqrt{1+\left(\dfrac{4PWK^2N_0^2S_{FL}}{7.75\ 10^6R}\right)^2}}=A+D+F$$

$$T_{rms}=(A^2+0.5B^2+0.048F^2+0.04AD+0.03DF)^{1/2}$$

$$N_{min}=N_0\left(1-\frac{T_{max}}{C}\right)$$

where

T_{max} = maximum torque imposed on the motor which is used in conjunction with the breakdown torque to determine the ability of the motor to carry the load under adverse conditions

T_{rms} = root-mean-square of the motor output, and is used to determine motor heating

N_{min} = minimum speed of the motor at the instant of heaviest load, and is used in estimating loom operation

A = friction torque

B = peak torque to accelerate lay

B' = peak torque to accelerate shuttle

P = number of picks per minute

Wk^2 = total system Wk^2 referred to motor

N_0 = motor synchronous speed

R = motor horsepower rating

S_{FL} = motor rated slip at full load

C = ratio of motor rated torque to rated speed

D = peak motor torque to drive lay

F = peak motor torque to drive shuttle

(See Appendix I for complete derivation)

Figure 12. Loom motor incorporating flywheel

All of the parameters, with the exception of friction torques, can be obtained by weighing and measuring, or are well known to loom designers. The friction must be estimated or determined by test. These equations lend themselves to fairly rapid columnar calculation, and, although only approximate, they are sufficiently accurate for motor application, as proved by comparison with oscillographic tests. By their use it is not difficult to compare the operation of motors with various combinations of characteristics, and to select the one with well-balanced performance.

Testing

Looms are tested to check motor operation and weaving ability, as outlined previously. In addition, tests can be used by the mill operator to determine that the loom fixer's adjustments hold friction and peak torques within limits anticipated by the loom designer.

From the oscillogram, Figure 8, it is apparent that watts input to the motor and the current input vary widely during different parts of the cycle. Ordinary meters connected to the circuit show wide needle swings and, unless properly read, give meaningless results. However, reliable results can be obtained if proper precautions and techniques are employed. Practical quantitative values descriptive of loom and motor operation are reduced from motor watt-input measurement and with due recognition of the two principles:

1. At any instant the input to the motor is the sum of motor output and motor losses.
2. Over a period of time, the average input to the motor is the sum of the average output plus the losses of the motor at the rms load.

Input can be measured in various ways, but the one that probably gives the greatest accuracy and the most complete information is an oscillographic recording of watts input to the motor. The oscillograph should be one that shows watts as an integrated curve and not as an envelope of an a-c wave. The average of the watt curve, Figure 8, is the average watt input to the motor and can be obtained by measuring ordinates or by means of a planimeter.

The rms of the watt trace can be calculated by measuring the ordinates, squaring them, averaging the squared values, and extracting the square root—a tedious process. The rms value also can be determined by the use of an Amsler mechanical integrator, a device that reads squared areas in the same manner that an ordinary planimeter reads areas; the rms value can be calculated as easily as the average.

The next step is to determine the watts loss of the motor. This can be done by referring to a test of the motor taken under steady load conditions, Figure 9, and determining the loss at the same watts input.

A curve such as Figure 10 is more convenient to work from. This is computed from efficiency data of Figure 9 and is a plot of watts input versus watts loss. In a similar manner, torque versus watts input and speed versus watts input also may be plotted, Figure 10. The average output of the motor is then the difference between average input watts and the watts loss, and can be converted to horsepower by dividing by 746, or to torque by multiplying by 7.04/average rpm. This is the friction torque of the loom.

Since the friction torque varies greatly, as illustrated in Figure 5, a comparison of motors on the basis of tested losses is fruitless unless the motor operation is referred to a common friction load. This is done by determining the difference, a, between the friction determined in a particular test and the accepted nominal value. Let rms_o be tested rms output of the motor, and let F_o be the tested average output. The corrected rms output, rms_c, is

$$rms_c = \sqrt{(rms_o)^2 + 2aF_o + a^2}$$

From the corrected rms output, the corrected losses are determined from the curve Figure 10, plotted from steady load conditions.

Peak values of torque and maximum and minimum values of speed can be determined, at least approximately, by entering Figure 10 with the proper ordinate of the watt trace.

Loom motors can be tested without the use of an oscillograph, with only a slight loss of accuracy and detail. The average watt input can be read on a polyphase wattmeter by reading the maximum and minimum positions of the needle as it swings through a rather wide range and then averaging the two readings. A better way is to use a watt-hour meter and count the revolutions of the disk for a minute or so, and get the average watts over this period of time.

The rms current can be measured with an ordinary electrodynamic or soft iron ammeter by noting the maximum and minimum positions of the needle and taking the reading halfway between the extremes. This is the rms value, since the scale of such an instrument is divided to read rms units. Calculations based on such test results are the same as outlined before, except that the rms load is determined from a current curve rather than from a watt curve. A hot-wire ammeter also can be used to advantage, since the needle swings are not as great as with the conventional type of indicating instrument. However, hot-wire instruments have practically no overload capacity, and are thus very prone to go out of calibration.

A fair approximation of peak torque can be obtained by measuring the peak value of watts input with a pointer-stop polyphase wattmeter. With this type of instrument, the needle is held up by an adjustable stop so that it moves from the stop only during the maximum part of the cycle. By using such a meter, the effect of the inertia of the meter itself is eliminated and a true peak value is observed. If a pointer-stop meter is not available, an ordinary instrument can be used by removing the cover glass and holding the needle in an elevated position with some small tool such as the blade of a penknife. This value of peak watts is used in the same manner as is that read from an oscillogram.

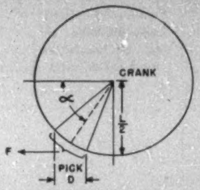

Figure 14. Diagram illustrating portion of crank cycle devoted to picking

A sample calculation of each type of measurement is given in Appendix II.

Effect of Wk^2

As explained before and as illustrated in Figure 7, the torque required to drive the loom is supplied in part from the power line and in part from the rotating parts of the system. The division of load varies depending on the amount of flywheel effect in the mechanical system and the slope of the motor speed–torque curve. Since the speed of the flywheel must drop to give up energy, it may be deduced that a motor with a sloping speed–torque curve is indicated. However, since the efficiency of a motor decreases with decreased speed and motor input, the sum of output and losses tends to increase. Thus, the gain expected from decreasing the load on the motor by letting the inertia do more work is offset to some degree by additional motor losses.

For this reason, a low-slip highly-efficient motor with high breakdown torque can be just as efficient, and give just as stable operation as one with greater Wk^2 but with lower efficiency, greater slip, and less breakdown torque. The operation of the loom is apparently exactly the same in both cases.

The addition of Wk^2 always reduces the amount of load on a motor of a given electrical design and reduces the motor losses as well as its speed variations when driving a pulsating load. The curve shown in Figure 11 illustrates how the losses of a given design of motor were reduced by the addition of Wk^2. It is apparent that the amount of reduction is appreciable, but the gains diminish after a reasonable amount of flywheel has been added. A motor with a built-in flywheel is shown in Figure 12.

The reduction in losses is so great that it often is entirely feasible to reduce the motor size one whole step and still satisfy the requirements of good motor application and loom operation.

Another consideration favoring inclusion of appreciable rotating inertia on the motor shaft is that 1,200-rpm motors may be substituted for 1,800-rpm motors without suffering an increase in speed variation.

This is not possible with conventional motors because the effective motor-rotor Wk^2, which varies with the square of the motor speed, is appreciably less when lower speed motors are used.

Motor Selection

In order to be sure that the motor will drive the loom without distress, two criteria are used:

1. The peak torque under maximum load on the motor should not exceed two-thirds of the breakdown torque of the motor.
2. The motor losses should not exceed the steady-state load losses which give a reasonable temperature rise.

By limiting peak torque to about two-thirds of breakdown torque, sufficient margin is provided to insure satisfactory operation under adverse conditions of 10 per cent under voltage and temporary load increase of about 20 per cent, as might be experienced during the loom break-in period. This safety factor assures that the speed will not drop so much that the picking becomes erratic.

Loom motors are rated 40 degrees centigrade rise on the windings at rated horsepower, this temperature being measured by thermometer during operation at rated load and under steady-state conditions. Traditionally, however, motors have been applied on the pulsating loom load to operate at about 55 degrees centigrade rise on the windings. (Overload protectors always have been selected in the range of 140–160 per cent of rated full-load current.) Although the method of rating and applying motors to looms differs from that for standard motors, the application specification that winding rise should not exceed 55 degrees centigrade is the same as for a conventional totally-enclosed motor. This is the maximum temperature rise considered for long trouble-free insulation life. As in any motor of this size, the outside temperature is considerably less than that of the winding and is generally in the 40 degrees centigrade rise range. Furthermore, this has become the practical limit in the minds of many, on the basis that a higher temperature affects the humidification around the loom. Therefore, a practical rule of application that insures meeting both requirements is to select a motor so that the temperature rise exceeds neither 40 degrees centigrade on the frame nor 55 degrees centigrade on the windings. Both temperatures are to be taken with mercury thermometers, or by an equivalent method.

The temperature rise of a motor on the loom cycle can be determined by comparing the rms losses, determined as outlined before, with the losses for a given temperature rise under steady-state conditions. This eliminates the necessity of conducting a heat run on the loom cycle.

Conclusions

1. The loom load is of a pulsating character, and the motor applied must have characteristics different from those of general-purpose machines Energy required at every instant must be supplied in part by electrical air-gap torque and in part from energy stored in the Wk^2.

2. Loom motors which give equivalent performance may be made with a wide range of designs, provided the characteristics are properly balanced.

3. The addition of a sizable flywheel reduces motor load, makes it possible to reduce the rating of the motor in some cases, and makes the operation of 1,200-rpm and 1,800-rpm motors equivalent.

4. Knowing only the basic constants of a loom and motor, performance of the combination may be calculated.

5. Motor tests on looms give results capable of reliable interpretation. Suitable instruments are:

a. An electrodynamic or soft-iron-type ammeter to read rms amperes.

b. A watt-hour meter or a polyphase wattmeter for reading average watts.

c. An a-c voltmeter to indicate line voltage. An oscillograph may be substituted for these three instruments for more precise results.

6. Friction load varies from loom to loom and from time to time on a given loom. This demands that a representative value of friction be established, and that all tests be corrected to a common base. In comparative testing, individual readings must be corrected to a nominal value before drawing conclusions.

Appendix I

This method of calculation is based on the assumption that the load consists of a constant part (broadly, friction), a sinusoid for accelerating the lay, and a single positive loop of an eighth harmonic for the pick. The torque is supplied electrically from the motor, and also from the flywheel. It further is assumed that the motor speed-torque curve is a straight line over the operating range.

The following must be known to make the calculation:

For the Loom

A = friction torque
H = weight of the shuttle
L = distance the lay moves
P = number of picks per minute
V = shuttle velocity as it leaves the box
W = weight of lay
$Wk_L^2 = Wk^2$ of the revolving parts of the loom (referred to the motor)

For the Motor

N_0 = synchronous speed of the motor
R = horsepower rating of the motor
S_{FL} = full load slip of the motor
$Wk_M^2 = Wk^2$ of the motor revolving parts
C = motor torque constant (see equation 13)

Additional Symbols

B = maximum torque to drive lay (4)
B' = maximum torque to pick shuttle (10)
E = energy of shuttle (5)
N = instantaneous motor speed (14)
N_{min} = minimum motor speed (27)
S = instantaneous motor slip
S_{FL} = full-load-motor slip (13)
S_0 = motor slip for friction (17)
S_1 = motor slip for lay (18)
S_2 = motor slip for pick (19)
T_{FL} = motor full-load torque (13)
T_L = torque to drive lay (4)
T_{max} = maximum torque motor delivers (24)
T_{rms} = rms torque motor delivers (26)
T_s = torque to drive shuttle (11)
Wk^2 = total Wk^2 referred to motors $= Wk_L^2 + Wk_M^2$ (14)
l = instantaneous movement of lay (1)
t = time
α = angle at which pick occurs (6)
θ = crank angle (1)
ω = angular velocity, radians per second, $= 2\pi P/60$ (1)
D = peak motor torque to drive lay (24a)
F = peak motor torque to drive shuttle (24a)

Torque to Drive the Lay

The lay is assumed to move in a straight line and to have an infinitely long connecting rod. See Figure 13.

The displacement of the lay from the center at any instant is

$$l = \frac{L}{2} \sin \theta = \frac{L}{2} \sin (1-S)P \frac{2\pi t}{60}$$

$$= \frac{L}{2} \sin (1-S)\omega t \qquad (1)$$

Acceleration of lay is

$$a = \frac{d^2l}{dt^2} = -\frac{L}{2}(1-S)^2\omega^2 \sin (1-S)\omega t \qquad (2)$$

Torque to drive the lay = −mass × acceleration × radius × cos θ

$$T_L = \frac{WL^2\omega^2(1-S)^2}{4_g} \sin (1-S)\omega t \cdot \times \cos (1-S)\omega t \qquad (3)$$

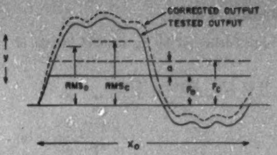

Figure 15. Correction for nominal friction

Since $(1-S)$ and $(1-S)^2 \cong 1$

$$T_L = \frac{WL^2P^2}{23500 \cdot N_0} \sin 2\omega t = B \sin 2\omega t \qquad (4)$$

Torque to Drive the Shuttle

The torque to drive the shuttle is assumed to be a single positive loop of an eighth harmonic.

Let

$$E = \text{energy of shuttle leaving the box} = \frac{HV^2}{2_g} \qquad (5)$$

E = average force × distance

and

$$\text{distance} = \left(\frac{1}{16}\right)(2\pi)\left(\frac{L}{2}\right) \sin \alpha = \frac{\pi}{16} L \sin \alpha \qquad (6)$$

(See Figure 14)

Therefore

$$\text{average force} = \frac{E}{\frac{\pi}{16} \sin \alpha} \qquad (7)$$

Torque = force × radius

$$= \frac{E}{\frac{\pi}{16} L \sin \alpha} \times \frac{L}{2} \sin \alpha = \frac{8E}{\pi} \qquad (8)$$

$$\text{Maximum torque} = \frac{\pi}{2} \frac{8}{\pi} E = 4E$$

(referred to crankshaft) (9)

Where

$$\frac{\pi}{2} = \frac{\text{peak}}{\text{average}} \text{ of sine wave}$$

$$\text{Maximum } T_s = \frac{4EP}{N_0} = B'$$

(referred to motor shaft) (10)

and

$$T_s = B' \sin 8\omega t \Big]_{\frac{3}{16}\frac{\pi}{\omega}}^{\frac{5}{16}\frac{\pi}{\omega}} \qquad (11)$$

that is, one positive loop of a sine wave extending from $t = 3/16$ to $t = 5/16$, since it is assumed that the pick occurs when the torque required to drive the lay is at a maximum.

Motor Electrical Torque

Electrical torque of motor = CS (12)

where

$$C = \frac{T_{FL}}{S_{FL}} = \frac{5250R}{S_{FL} N_0} \qquad (13)$$

Moment of Inertia

Torque delivered by moment of inertia of system

$$=\frac{Wk^2}{306}\frac{dN}{dt}=\frac{Wk^2N_o}{306}\frac{d(1-S)}{dt}=$$

$$-\frac{Wk^2N_o}{306}\frac{dS}{dt} \qquad (14)$$

$$=-I\frac{dS}{dt}$$

where

$$I=\frac{Wk^2N_o}{306} \qquad (15)$$

Maximum Torques

Equating the expression for total load torque with that for total driving torque

$$A+B\sin 2\omega t+B'\sin 8\omega t=CS-I\frac{dS}{dt} \qquad (16)$$

Since the equation is linear, it can be broken down to

$$A=CS_o \qquad (17)$$

$$B\sin 2\omega t=CS_1-I\frac{dS_1}{dt} \qquad (18)$$

$$B'\sin 8\omega t=CS_2-I\frac{dS_2}{dt} \qquad (19)$$

$$S=S_o+S_1+S_2 \qquad (20)$$

The similarity of equations 18 and 19 to the usual equation of harmonic current is apparent. The symbols of equations 21 and 22 are the usual electrical ones.

$$E\sin\omega t=iR-L\frac{di}{dt} \qquad (21)$$

The solution given in any text on alternating currents is

$$i=\frac{E}{\sqrt{R^2+(L\omega)^2}}\sin\left(\omega t-\tan^{-1}\frac{L\omega}{R}\right) \qquad (22)$$

By comparison, the following can be written from equations 17 through 22

$$T=A+\frac{BC}{\sqrt{C^2+(2I\omega)^2}}\times$$

$$\sin\left(2\omega t-\frac{1}{2}\tan^{-1}\frac{2I\omega}{C}\right)+$$

$$\frac{B'C}{\sqrt{C^2+(8I\omega)^2}}\sin\left(8\omega t-\frac{1}{8}\tan\frac{8I\omega}{L}\right) \qquad (23)$$

$$T_{max}=A+\frac{B}{\sqrt{1+\left(\frac{PWK^2N_o{}^2S_{FL}}{7.75\cdot 10^6R}\right)^2}}+$$

$$\frac{B'}{\sqrt{1+\left(\frac{4PWK^2N_o{}^2S_{FL}}{7.75\cdot 10^6R}\right)^2}} \qquad (24)$$

$$=A+D+F \qquad (24a)$$

Rms Torque

The equation of rms torque is

$$T_{rms}=\left(\frac{\omega}{2\pi}\left[\int_0^{\frac{3}{16}\frac{\pi}{\omega}}(A+D\sin 2\omega t)^2dt+\right.\right.$$

$$\int_{\frac{5}{16}\frac{\pi}{\omega}}^{\frac{2\pi}{\omega}}(A+D\sin 2\omega t)^2dt+$$

$$\left.\left.\int_{\frac{3}{16}\frac{\pi}{\omega}}^{\frac{5}{16}\frac{\pi}{\omega}}(A+D\sin 2\omega t+F\sin 8\omega t)dt\right]\right)^{1/2}$$

$$(25)$$

which reduces to

$$T_{rms}=(A^2+0.5D^2+0.048F^2+$$

$$0.04AD\quad 0.03DF)^{1/2} \qquad (26)$$

Minimum Speed

$$\text{Minimum speed}=N_{min}=N_o\left(1-\frac{T_{max}}{C}\right) \qquad (27)$$

Correction of Motor Rms Output to Nominal Friction

Refer to Figure 15.
Let

F_o = friction as tested
F_c = nominal friction
rms_o = Root mean square of output as tested
rms_c = Root mean square of output as corrected

$$a=F_c-F_o \qquad (28)$$

By definition

$$rms_o{}^2=\int_0^{x_o}\frac{y^2}{x_o}dx \qquad (29)$$

and

$$F_o=\int_0^{x_o}\frac{y}{x_o}dx \qquad (30)$$

Then

$$rms_c{}^2=\int\frac{(y+a)^2dx}{x_o}=\int\frac{y^2}{x_o}dx+$$

$$2a\int\frac{y}{x_o}dx+a^2\int\frac{dx}{x_o} \qquad (31)$$

$$=rms_o{}^2+2aF_o+a^2 \qquad (32)$$

$$rms_c=\sqrt{rms_o{}^2+2aF_o+a^2} \qquad (33)$$

Appendix II. Sample Calculation of Test Results

Test Data

1. Motor rating = $1^1/_2$ horsepower
2. Picks per minute = 202
3. Average watts (oscillogram) = 1,600
4. Average watts (indicating meter) = 1,620
5. Rms watts (oscillogram) = 2,160
6. Rms amperes (indicating meter) = 6 5

Calculation of Oscillogram Test

7. Watts loss (Figure 10) = 305
8. Average output = 1,600 − 305 = 1,295
9. Average torque = $\frac{1,295}{746}\times\frac{5,250}{1,750}=5.25$
10. Rms torque (Figure 10) = 7.5
11. Assumed average torque at 202 picks (Figure 10) = 5.00
12. Average torque correction, $a=5.00-5.25=-0.25$
13. Corrected rms torque = $rms_c=\sqrt{7.5^2-2(0.25)(5.25)+(0.25)^2}=7.4$
14. Corrected losses (Figure 10) = 295

Calculation of Indicating Instrument Test

15. Horsepower at 6.5 amperes (Figure 9) = 2.5
16. Efficiency at 2.5 horsepower (Figure 9) = 0.86
17. Rms loss = $2.5\times 746\ \frac{(1-.86)}{.86}=305$ watts
18. Average ouput = 1,620 − 305 = 1,315 watts

Then proceed through steps 9 to 14 inclusive.

A Manually-Operated Spring Mechanism for Medium Voltage Oilless Circuit Breakers

B. W. WYMAN
MEMBER AIEE

E. J. CASEY
MEMBER AIEE

Synopsis: Magnetic oilless circuit breakers rated 2,300 to 15,000 volts require high contact closing speeds in order to prevent excessive arcing during closing. As these contact speeds cannot be obtained manually, it has never been possible to operate magnetic circuit breakers of this class by manual mechanisms of the type frequently used to operate oil circuit breakers. In every case where medium voltage magnetic circuit breakers were applied, it was necessary, therefore, to install a reliable source of closing power. This requirement constituted a serious application handicap in some locations where a reliable source of closing power (normally storage batteries) is difficult and expensive to install. This paper describes a new type of mechanism for operating magnetic oilless circuit breakers rated 2,300 to 15,000 volts, which has been developed especially for such applications. Energy is manually supplied to this mechanism where it is stored in heavy compression springs until it is released to close the circuit breaker. Unlike previous mechanisms, when this mechanism is released, the springs transfer their energy to a rotating mass which in turn drives the circuit breaker contacts. As this rotating mass accelerates until the circuit breaker contacts meet, its entire energy is available for closing and latching the circuit breaker against the magnetic retarding forces of high current short circuits if the circuit breaker should be closed accidentally on a faulted circuit.

FROM the beginning of the electrical industry, many indoor oil circuit breakers, rated 15 kv and below, have been closed manually by hand-operated lever-type mechanisms. This type of operation was generally successful as long as short circuit currents were small. When short circuit currents increased to a certain value, however, the closing force and speed which an operator could supply manually were inadequate to close and latch the circuit breaker without stalling at the moment the contacts touched due to the high magnetic retarding forces of the short circuit current through the contacts. As these magnetic retarding forces varied as the square of the short circuit current, higher values of current actually reversed the motion of the contacts during the closing stroke. This sometimes resulted in excessive pressures being generated within the circuit breaker tank. For safety to personnel, therefore, the application of oil circuit breakers with manual mechanisms was limited to those locations where the maximum available short circuit current did not exceed 12,500 amperes. In locations where the available short circuit current exceeded this value, solenoid or other types of power operated mechanisms were used.

When magnetic air circuit breakers were developed for these voltages, it was found that higher closing speeds were necessary than had been common with oil circuit breakers to minimize arc prestriking between the contacts during closing. This was due to the lower dielectric strength of the air between the contacts as compared to oil in the oil circuit breakers. This meant that these oilless circuit breakers could not be operated by lever-type manual operating mechanisms even on load currents, and electrical operation was essential. Electrical operation was obtained on most magnetic oilless circuit breakers by means of solenoid mechanisms. In January 1946, a special solenoid mechanism using a flux shifting double air gap principle with high final output force was described before the Institute, which was capable of closing and latching magne-blast circuit breaker contacts on short circuit currents up to the full momentary current rating of the circuit breaker without disturbance or stalling of contacts.

Any solenoid mechanism, however, requires a reliable source of control power. As the most reliable source of power was normally considered to be storage batteries, they were used wherever possible. For isolated applications where storage battery installations were impractical, rectified alternating current from a control power transformer was used. Where these happened to be incoming line circuit breakers, however, the control power transformer had to be connected ahead of the circuit breaker in order for it to be energized when the circuit breaker was open.

This practice had the disadvantage that the circuit breaker afforded no protection in case of a short circuit in the control power transformer. For such isolated locations therefore, manual closing was desirable if some type of manual mechanism were available which had output force and speed characteristics similar to the output force and speed characteristics of the special high force solenoid mechanisms. A manual mechanism fulfilling these requirements obviously could not be of the simple hand-lever type, but would have to be of a stored energy type in which the charging energy could preferably be supplied by hand.

As magnetic air circuit breakers became more and more generally used in utility applications, various utility groups, such as the Edison Electric Institute and the Association of Edison Illuminating Companies, outlined the necessity for some type of manually operated stored energy mechanism which could be used to close magnetic-type oilless circuit breakers for locations where a satisfactory electrical

B. W. WYMAN and E. J. CASEY are with the circuit breaker division of the General Electric Company, Philadelphia, Pa.

control power source could not be obtained.

Requirements for Mechanism

In initiating the development of a manually operated stored energy mechanism to close magne-blast circuit breakers, the following requirements were established:

1. The mechanism should close the circuit breaker contacts with a closing speed at least equal to, or greater than 10 feet per second.

2. The mechanism should possess sufficient energy to not only close and latch the circuit breaker contacts on normal load currents, but also should close and latch the circuit breaker contacts without disturbance if the circuit breaker were closed accidentally on a short circuit up to the momentary current rating of the circuit breaker.

3. The mechanism should be capable of closing the circuit breaker with a minimum of time and effort on the part of the station attendant.

4. The mechanism should be sufficiently compact to be mounted on the front of the magne-blast circuit breaker without interfering with its installation in the metal-clad switchgear unit.

5. For safety to station attendant, the mechanism should be capable of closing and latching the circuit breaker with the door of the metal clad switchgear unit closed.

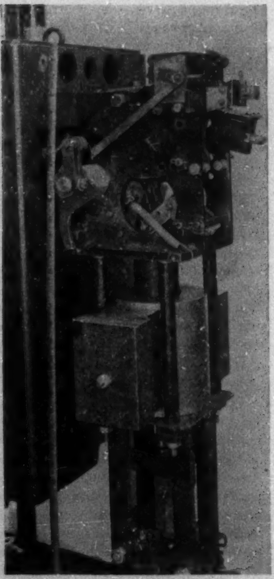

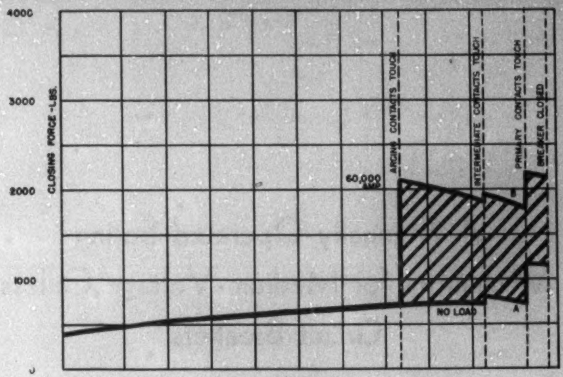

Figure 2. Closing force required at magne-blast circuit breaker linkage

A. Closing no-load. B. Closing against 60,000 amperes short circuit

Analysis of Possible Types of Mechanism

As it was realized that some source of stored energy would be necessary to meet the foregoing requirements, several sources of stored energy were considered. Among these were: a piston driven by high-pressure bottled gas; a piston driven by gun powder; a manually-charged spring which, when charged and released directly, drives the circuit breaker contacts; a manually-charged spring which, when charged and released, drives a mass which stores energy, and in turn drives the circuit breaker contacts. Table I lists some of the advantages and disadvantages of the various types of stored energy mechanisms which were considered.

A careful evaluation of the advantages and disadvantages of each type was made from the standpoint of: reliability; operation; maintenance and service; and manufacturing. To obtain a comparison from an operational standpoint

Table I. Comparison of Stored Energy Mechanisms

Type	Advantages	Disadvantages
1. Piston driven by gun powder	Light weight, compactness, pressure of 3,500 to 5,000 psi obtained. Burning gun powder permits small piston.	Extremely rapid burning of powder necessitates very large mass to store energy. Cylinder corrosion from high-temperature gases, requiring cleaning after operation. Gun powder must be kept in form of cartridges at all times.
2. Piston driven by high-pressure bottled gas	Compactness, ample energy and availability.	High-pressure gas must be kept available at all times. Available energy varies with temperature.
3. Direct spring drive	Simplicity, constant availability, and dependability.	Produces extremely high contact speeds. Produces greatest force at beginning of stroke, has little force at contact closing when required.
4. Spring-driven rotating mass	Simplicity, constant availability, and dependability. Capability of delivering full force at point of contact closing enabling circuit breaker to close and latch high momentary currents. Smoothness of closing operation. Instantaneous reclosing operation possible by energy stored.	Somewhat larger size and weight.

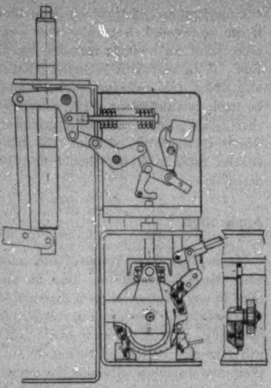

Figure 3. Cross section of manually-charged spring mechanism showing rotating mass driving crank shaft and connecting rod to supply closing energy to trip-free magne-blast circuit breaker linkage shown at top

between the various sources of stored energy, experimental samples of each type were built and tested. The most compact mechanism tested was the gun powder driven piston mechanism. Due to the fact that pressures up to 5,000 pounds per square inch are available from the gun powder, a very small piston could be used. Because of the extremely rapid burning rate of the gun powder, however, it was found on this mechanism that a mass had to be added which could be accelerated by the gun powder, and this mass then used to carry the circuit breaker closed, as shown in Figure 1. The disadvantages of this type of mechanism, which are listed in Table I, however, outweighed the advantages when compared with some of the experimental mechanisms using other sources of stored energy. A study of the advantages and disadvantages of each type built indicated that the spring-driven mass mechanism was the most desirable type for further development.

Development of Mechanism

In addition to satisfying the requirements already established, the output force supplied by the spring-driven mass mechanism must match the force requirements of the circuit breaker over the entire closing stroke, both when the circuit breaker was being closed on no-load, and when it was being closed on a faulted line with the maximum short circuit current flowing. Figure 2(A) shows the required force curve when closing the circuit breaker against no-load. It will be noted that the required closing force increases abruptly near the end of the closing stroke due to the heavy contact pressure. The abrupt increase in closing force required is the primary reason that the operating characteristics of the spring-driven mass mechanism are so superior to the direct-spring drive. With the direct-spring drive, most of the energy stored in the springs was already dissipated by the time the contacts touched. With a mass interposed, most of the spring energy in the first part of the stroke when the springs are fully compressed, goes into accelerating the mass, and all this energy is later available at the end of the stroke to overcome the contact pressure. The area under the force curve "A" in Figure 2 is the total energy required from the mechanism. Curve "B" in Figure 2 shows how this force curve is modified when the circuit breaker is closed on a short circuit current equal to the momentary current rating of the circuit breaker. It will be noted that the high magnetic retarding forces of the short circuit current through the circuit breaker contacts increase considerably the required force near the end of the closing stroke. The increase in area under this curve over that in curve "A" shown by the crosshatched area, represents an additional 1,010-inch pounds which must be available in the mechanism in order to prevent the circuit breaker contacts from stalling if they should be closed accidentally on a short circuit equal to 60,000 amperes. As the retarding force varies with the square of the short circuit current, this crosshatched area would increase to 1,800-inch pounds at 80,000 amperes. If the mechanism does not have available this amount of excess energy, the circuit breaker contacts would stall when trying to close against a short circuit, resulting in excessive arcing before the circuit breaker trip coil could operate to reopen the circuit breaker, possibly with disastrous consequences.

Under conditions of light load, or no-load, the excess energy which is provided for short-circuit conditions must be absorbed in some manner in the mechanism itself. As most of the circuit breaker operations will be under light load, or no-load, it is highly desirable that this excess energy be absorbed without shock to the mechanism or circuit breaker. The simplest manner of accomplishing this is to store the energy in rotation of the mass so that it acts as a flywheel to operate a crank shaft, and raise the mechanically trip-free circuit breaker linkage up on its prop, as shown in Figure 3. After the circuit breaker linkage has been raised up on its prop, the mass continues to rotate a partial revolution, thereby putting some compression back into the springs. The next manual charging of the springs, therefore, requires less energy input. If, however, the circuit breaker had closed on a heavy short circuit on the previous operation, there would be very little excess rotational energy left in the flywheel, and the next manual charging would have to supply almost the total spring energy. As this manual charging is obtained from a simple hand jacking on the rotating mass, it means that a few extra strokes will be required on the next operation. As the crank shaft motion

Figure 4A. Travel curve of circuit breaker contacts and crank shaft connecting rod when closing the magne-blast circuit breaker on no-load

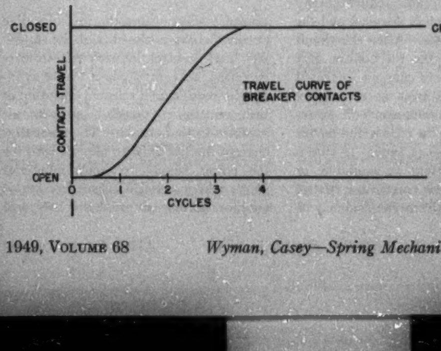

Figure 4B. Travel curve of circuit breaker contacts and crank shaft connecting rod when closing the magne-blast circuit breaker against a short circuit current of 60,000 amperes simulated by precompressed springs

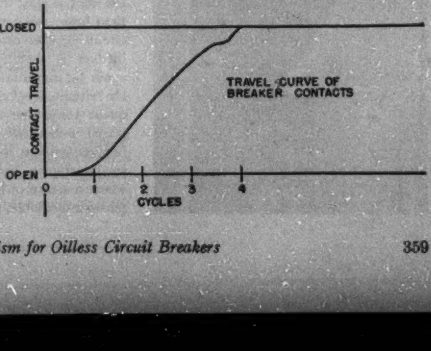

Figure 5. Magne-blast circuit breaker equipped with manually-charged spring operating mechanism ready for installation in metal clad switchgear. Charging handle shown in position

raising the crank linkage on its prop is a smooth (1-cosine) curve, this arrangement produces an extremely smooth operation of the circuit breaker contacts, both when closing against no-load and full short-circuit current. It eliminates the necessity of any buffers or dashpots required with most mechanisms, because the velocity of the contacts reduces smoothly to zero as the crank shaft reaches its uppermost position.

Figure 4(A) shows the travel of the circuit breaker contacts when closing against no-load. To determine the proper ratio of mass and compression springs to be used for the best over-all operation, tests were first made in which the short circuit magnetic retarding forces on the contacts were simulated by heavy additional springs fastened to the contacts. Figure 4(B) shows the travel of the circuit breaker contacts when closing against this extra retarding load with the ratios of spring and mass which were finally established for best operation. It will be noted that no stalling occurs in the contact travel when closing in against the maximum retarding force, and that actually only a very slight deviation can be seen between the travel at no-load and full retarding load.

Figure 6. Manual charging operation of spring mechanism on magne-blast circuit breaker installed in vertical lift metal clad switchgear and raised to operating position

After the best ratio of spring and mass had been determined, complete series of short circuit closing tests were made on the magne-blast circuit breaker with the circuit breaker closing and latching against fault circuits varying from no-load up through the momentary short circuit rating. A partial summary of these tests is shown in Table II. In these tests, the circuit breaker closed successfully and latched currents up to 92,000 amperes without excessive arcing at the contacts. As the mechanism uses the same mechanically trip-free linkage as is used on solenoid-type magne-blast circuit breakers, the tripping characteristics are unchanged, and the normal tripping time from trip impulses to interruption time varies between four and five cycles. Any standard means for tripping the magne-blast circuit breaker may be used when operated by this manually-charged spring mechanism; such as d-c potential trip, a-c potential trip, or instantaneous overcurrent trips energized by current transformers. Figure 5 shows a magne-blast circuit breaker equipped with a manually-charged spring mechanism.

Operation

Normal operation of the manually-charged spring mechanism is to first manually charge the springs by the jacking motion, as shown in Figure 6, which rotates the mass carrying the crankshaft just over center against a latch. To close the magne-blast circuit breaker at any time later, this latch is released and the circuit breaker closes. After the circuit breaker is closed, the mechanism may again be immediately charged so that if the circuit breaker trips at any subsequent time, the mechanism can be released immediately to reclose the circuit breaker without loss of time. In case a small tripping battery is available, or where a source of low current a-c control power is available, the mechanism may be equipped with an electrical release, so that it can be released electrically from a remote point for a single reclosing operation. If an automatic reclosing relay is also added, this reclosing operation may be made instantaneous. The extremely short closing time of the mechanism (three cycles after releasing the trip) enables rapid reclosing should that be desirable.

Application

Magne-blast circuit breakers with manually-charged mechanisms may be applied in any location where a dependable source of closing power is not available for operating solenoid mechanisms. This will generally be limited to remote stations, and usually to incoming line circuit breakers only. After the incoming line circuit breaker is closed, and the station bus and control power transformers energized, a-c control power will be available for rectifier and solenoid operation of the remaining magne-blast circuit breakers in that station. The manually-charged mechanism also may be used for the power supply to small industrial plants where a single circuit breaker is used for short circuit protection only, and

Figure 7. Magne-blast circuit breaker equipped with manually-charged spring operating mechanism removed from vertical lift metal clad switchgear

Table II. Short Circuit Test Data

3-Phase 60-Cycle Closing and Latching Tests

Test	Current Maximum Loop Peak	Current Maximum Loop Rms	Closing Speed, Feet Per Second	Degrees Excess Mass Rotation to Recharge Spring
1	1,130	680	16	67
2	1,250	750	16	66
3	65,000	39,000	16	62
4	69,000	42,000	16	67
5	87,000	51,000	16	62
6	87,000	51,000	16	62
7	105,000	61,000	16	54
8	100,000	63,000	16	54
9	152,000	92,000	16	41

where a control battery installation is not justified.

Summary

By means of the new manually-charged spring mechanism, magnetic oilless circuit breakers rated 2,300 to 15,000 volts for the first time may be applied where no dependable source of electrical control power is available. The output force of this mechanism is such that it will close and latch magne-blast circuit breakers against their full momentary current rating without excessive contact arcing, or without danger to operating personnel. Despite the high output force available, this mechanism is so designed that it absorbs without shock all excess force not required by the circuit breaker when it is closed on no-load, and therefore provides extremely smooth operation.

Discussion

Robert H. Nau (University of Illinois, Urbana, Ill.): I appreciate and am very much interested in the story of the development of the mechanically-stored-energy closing mechanism for the magne-blast circuit breaker of the General Electric Company. The given information is apparently accurate, and is quite convincing in that any remote installation may be assured the acme of protection by the "extremely smooth operation" of the main magne-blast circuit breaker on the incoming circuit.

Inasmuch as I and many other design and development engineers are fairly well informed, theoretically, concerning the perversity of kinetic energy of a moving mass I ask the authors to give to us, a complete technical discussion of the total mechanism used to impart the kinetic energy to a moving mass. That part of the mechanism used to harness this kinetic energy and hence deliver the positive closing-force to the hinged or pivoted contacts should be discussed. In order to clearly illustrate the action, I further ask the authors to support their discussion by sufficiently detailed elevation drawings, with legends.

By the general text of the paper, I gather that the mechanism is adequate to positively close the magne-blast circuit breaker only once against the optimum short circuit for each charge of hand-pumped mechanically-stored energy. Is this correct? I ask because the text in the section on "Operation" might give reason for implication that two closings per hand-pumped charge may be expected. I suspect that the authors meant to include that the circuit breaker would respond to a reclosure provided the station operator went to the particular circuit breaker and hand charged the mechanism after the circuit breaker had been closed, but before the circuit breaker was called upon to perform the reclosure cycle.

I ask another question. Can you now build or do you have the data for building one of the mechanically-stored-energy closing mechanisms for the magne-blast circuit breaker which will provide two closings of the circuit breaker on one hand-pumped charge for each of the conditions:

1. Both closures being against the optimum short circuit?
2. The first closure against rated full-load, and the second against optimum short circuit?

One more question. How will the 1-closure and the 2-closure mechanisms compare in space requirements, in weight, and in cost to the customer?

Knute Falck (Philadelphia Electric Company, Philadelphia, Pa.): The spring-operated mechanism described in this paper meets a real need. This may be further emphasized by pointing out that one of the major applications would be on customers' installations with single service. In most such cases the use of a battery is undesirable both from the cost and maintenance angle. Rectifier closing requires a tap on the line side of the circuit breaker which also is objectionable and introduces a metering problem. In general, the same difficulties are present in the power companies' own isolated installations.

The authors' method of analysis of the problem is thorough and systematic and their selection of this particular type of spring mechanism appears wise. The consideration given to the ability of the circuit breaker to close against a short circuit is well justified because the inherent characteristics of air circuit breakers of this voltage class are such that manual closing is unsafe, and if the circuit breaker mechanism is not capable of closing the circuit breaker against a short circuit, then it is no longer a truly protective device but a hazard.

Judging from the paper, it is believed that the spring mechanism subjects the structure to less shock and vibration than a solenoid mechanism, but it may be possible that the forces have been redistributed sufficiently to unbalance the previous over-all design and cause relay contact troubles. Has this been thoroughly tested?

One of the requirements listed is that the mechanism should be capable of closing and latching the circuit breaker with the door of the metalclad switchgear unit closed. The text refers to the jacking operation illustrated by Figure 7. This figure shows the door open. Is it correct to assume that the requirement has been met and that the door may be closed and the circuit breaker closed from the outside?

Has consideration been given to developing this type of mechanism for higher-voltage circuit breakers possibly including a motor operated charger?

The general impression of this mechanism is that it represents an effective application of fundamentally sound principles.

J. Stanley Brown (Duquesne Light Company, Pittsburgh, Pa.): The device discussed appears to be a practical solution to a problem that is sometimes met in practice.

We have recently had occasion to view with interest, a "bottle" operated mechanism for operation of 34.5-kv interrupter-type disconnecting switches. It performed very well. There is the possibility for application of a manually-stored energy closing and tripping device in this field because there is no place for operator hesitancy in operating disconnecting switches equipped with plunger or other type of interrupter units.

This new closing device, when proved in use, should be made available on competitive equipment.

It seems objectionable to be required to open the cubicle door to be able to manually charge the spring. This objection should be relatively easy for the designers to overcome.

Apparently the amount of stored energy left over after a normal closure is adequate for another normal closure, but not enough for a closure into a maximum fault. Therefore, if it is desirable to leave the circuit breaker set up for reclosure, the spring should be fully charged by the operator after the initial closing of the circuit breaker. This all then would seem to require some foolproof manner of assuring that the operator fully charges the spring. This subject is not clarified by the authors in their paper.

The powder- and bottle-operated mechanisms have appeal in those cases where it is desirable to leave the circuit set up for one or more reclosures. In the case of the powder-operated mechanisms, fouling should not be a problem when the proper ammunition is used.

Apparently, the greatest advantage of the accelerated mass design is associated with the self-snubbing shape of the closing curve permitted by the crank shaft action, while still permitting near maximum force to be available at the same time.

The authors should be complimented on their disclosure.

H. V. Nye (Allis Chalmers Manufacturing Company, West Allis, Wis.): This paper covers an interesting development of a manually-operated spring-closing mechanism for magnetic circuit breakers of the oilless type, for use in locations where no other means of operating power is available. Specifically designed for these locations as described in the paper, the mechanism seems to meet all of the requirements for such a device.

The discussion of alternative types of mechanism is interesting and indicates that considerable investigation of a gun powder operated mechanism was undertaken. The paper does not disclose, however, that an equally exhaustive investigation of a bottled-gas operator was conducted.

It seems to the writer that the mechanism described in this paper, although adapted to the application outlined, does not meet the need for an emergency closing device which can be applied to operate a solenoid-operated circuit breaker in case of control power failure or solenoid failure. The need for such an emergency closing device seems amply evident from the number of engineers who are asking for it. The spring-closed mechanism of this paper makes an excellent alternative closing mechanism but is distinctively an alternate to solenoid closing.

The disadvantages listed for the bottled-gas-driven piston are perhaps distinct disadvantages for any mechanism which is to be used for normal operation, but I cannot see that they are of importance if this method of operation is applied to an emergency closing device where a continuous and considerable supply of the operating gas is by no means essential.

To the advantages of this type of device can be added the statement that it is capable of being made as an auxiliary device for use in case of the failure of the source of power usually depended on, due to the compactness of the device and the facility with which it can be combined with a solenoid operated mechanism.

Consequently, it is my belief that circuit breaker engineers still have the problem of producing an auxiliary closing device that can be applied to the usual solenoid mechanism for emergency operation. Bottled-gas operation seems to be a distinct possibility for such an auxiliary operator, but does not preclude the use of other means. It does seem, however, that such a device must be very compact and comparatively inexpensive, and I believe the use of bottled gas has decided advantages from the standpoint of economy and availability.

Looking over the diagram showing the closing force required for closing in against a fault current compared with no-load operation, Fig. 3 of the paper will serve to impress on the reader the magnitude of closing force which must be available for such operation. It illustrates the problem a circuit breaker designer has in having this force available and yet controlling the operation under normal conditions so that the impact will not injure the operating mechanism or breaker. It might have been interesting to bring out the extent to which these required force variations can be equalized for the operator by the proper arrangement of levers and rotating centers in the mechanism itself. The methods employed in absorbing excess energy at the end of the closing stroke are also very important and might have been discussed.

C. E. Winegartner (Cleveland Electric Illuminating Company, Cleveland, Ohio): This manually-charged spring mechanism almost fills a long-felt need for a reliable source of closing power at a remote station with only a few circuit breakers, without the necessity of installing and maintaining a control battery. Almost, because it leaves the art of a-c tripping, without much needed improvement. If tripping batteries must be provided, then some of the advantages of manual closing is lost.

Either the contacts of circuit opening protective relays should be improved so that they can rupture without excessive maintenance the maximum short-circuit currents to which they may be subjected, or some form of network transformer should be developed into which the current transformers would feed, and the output used for tripping through protective relay contacts. With such improved a-c tripping, this manual operator promises better and more economical power supply to isolated load centers served by a few circuit breakers, with the improved service of a 1-shot reclosure, and without a battery problem.

B. W. Wyman and E. J. Casey: The authors are extremely gratified with the widespread interest which has been exhibited in the spring mechanism recently developed to manually operate the magne-blast circuit breaker. The discussions indicate that some points were not made entirely clear in the paper. Nye and Brown have both brought up the subject of the feasibility of operating with bottled gas rather than springs. The authors agree with Nye that there may be a place for bottled-gas operators for emergency operation of solenoid or compressed-air mechanisms. It is extremely doubtful, however, whether many station attendants would care to use bottled gas as a regular thing for all operations of a circuit breaker which had no source of electrical control power. To provide such operation with bottled gas, would require an appreciable reserve storage capacity of bottled gas maintained at all times to insure continuity of service during storm periods when a large number of trip-outs may follow each other in a short period of time. For manual operation under these conditions, the spring operator which can be charged by hand offers a distinct advantage.

Brown also questions whether some means of foolproofing has been added into the operation of the mechanism to prevent closing if the springs have not been completely charged. This is taken care of inherently in the design by the rotating mass starting position which must be at the upper end of the crank shaft motion to be released to close the circuit breaker. In this position the springs are always in the fully charged position, and therefore capable of closing and latching the circuit breaker against the maximum short-circuit current rating of the circuit breaker. This feature makes the mechanism more foolproof than any other possible method because the mechanism can not be released until the springs have been fully charged.

The charging operation illustrated in Figure 7 shows a man, manually charging the springs prior to closing the circuit breaker with the door of the metal-clad compartment closed. He would then close the door before releasing the springs to close the circuit breaker so that he would be afforded the full protection of the metal-clad structure during any operation of the circuit breaker.

Falck has questioned whether the jacking motion may be performed also while the door is closed. To do this would require a slot in the door for the manual handle to enter which could be included in any installation where this was considered desirable. The reduced amount of shock which this circuit breaker affords during a closing operation has been thoroughly tested to insure that it will not cause faulty operation of relays mounted on the equipment door. The primary reason for the reduction in shock is that excess energy is absorbed smoothly in the springs without being transmitted either to the circuit breaker frame or equipment structure. A-c tripping is possible without auxiliary tripping batteries through the use of over-current a-c trip coils mounted on the front of the mechanism if d-c tripping batteries are not available. Such trip coils provide accurate, positive operation on short-circuit currents where the magnitude of the current is high. They may however be less positive in their pick-up on overload currents near the pick-up point.

Nau questions whether two closing operations may be accomplished with this mechanism from one manual jacking of the springs. The inherent design of the mechanism is such that one closing operation is provided by each release of spring energy during a revolution of the rotating mass. Only one closing operation may therefore be obtained from each manual charging operation. As pointed out in the paper, this charging operation of the springs is independent of the position of the circuit breaker and the springs may be recharged after the circuit breaker is closed and latched. This energy is stored ready to reclose the circuit breaker immediately following a trip-out at any later time. This reclosing operation could be initiated automatically by reclosing relays, providing a small battery were available to release the spring latch.

A New 69-Kv Compressed-Air Circuit Breaker

B. P. BAKER
FELLOW AIEE

E. FRISCH
MEMBER AIEE

Synopsis: A metal-enclosed 3-phase 69-kv 3,500,000-kva 2,000-ampere compressed-air circuit breaker of the orifice type has been developed for outdoor service. The metal enclosure has six condenser bushings extending through the roof for connecting the circuit breaker terminals to the metal-clad bus structure. Each pole of the circuit breaker consists of an air reservoir, blast valve, isolating switch, and an interrupter. The interrupter assembly includes a moving-contact assembly, two orifice-type stationary contacts, and two exhaust gas receiving chambers, all clamped together by four spring-loaded wood Micarta rods. The isolating switches of the three poles are gang-operated by a single pneumatic mechanism mounted on the air reservoir of the center pole.

This circuit breaker has successfully passed all its commercial tests and has interrupted 37,500 amperes with 44 kv across a single pole.

IN LARGE metropolitan districts, such as Chicago, Philadelphia, and New York, the increasing power requirements of the congested residential and business districts necessitate the use of higher voltages for economical transmission and power distribution.

As the voltage increases, the necessary precautions to protect the power company personnel and the public from the attendant hazards become increasingly difficult and exacting. Not only must direct contact with the electric equipment be prevented and the danger of fire be reduced to a minimum, but it also is necessary that the operation of the equipment does not produce noise, radio interference, visible flashes, or other effects which in any way are annoying or disturbing to the public. In addition, outages must be limited to minimum, fault disturbances must be localized as much as possible, and the equipment must require only infrequent servicing and inspection. A practical solution for satisfying these requirements is offered by outdoor metal-enclosed switchgear which has gained wide acceptance.[1] Although the first cost is somewhat higher than for conventional equipment, it can be justified on the basis of lower installation cost, higher safety, fewer service interruptions, and reduced maintenance.

For a pioneering installation of this type on a 69-kv system capable of delivering 3,500,000 kva under fault conditions, the choice of a circuit breaker required considerable study. In general, there has been a tendency in this country to use compressed-air circuit breakers for indoor powerhouse service up to 34.5 kv, while oil circuit breakers are used for outdoor service up to the highest voltages. Since the circuit breakers for this installation will be installed outdoors, the normal selection, according to this practice, would have been the outdoor oil circuit breaker. Other considerations and requirements made it desirable, however, to extend the range of the indoor compressed-air circuit breaker and mount it in a weatherproof enclosure for this service.

Very satisfactory experience has been obtained with 34.5-kv indoor compressed-air circuit breakers when mounted in weatherproof metal housings for outdoor service. Also, several special 12-kv high-speed compressed-air circuit breakers have given an excellent account of themselves on the Pennsylvania Railroad system.[2] These circuit breakers, of indoor design, are placed in metal enclosures and installed outdoors.

Historical Review of Compressed-Air Circuit-Breaker Practice

The compressed-air circuit breaker first made its appearance about 20 years ago in Europe, where high cost of materials and low labor cost favor this type of circuit breaker. As a result, the efforts in Europe have been concentrated mainly on the development of compressed-air circuit breakers.

In this country, where conditions and requirements are different, oil circuit breakers are used for practically all high-voltage outdoor service and are available for up to 10,000,000-kva interrupting capacity.[3] Practically all development of compressed-air circuit breakers has been directed toward heavy-duty indoor powerhouse applications because of the insistent demand for reduction in fire hazard for this service. Circuit breakers of this type are available for 15-kv and 34.5-kv service with interrupting capacities of 2,500,000 kva. This line of circuit breakers,[4,5] with a 10-year service record, has proved very satisfactory and has received general acceptance as standard equipment.

For compressed-air circuit breakers, the orifice or nozzle type has become the general design practice in Europe where the kilovolt-ampere requirements are comparatively low. In this country, however, the cross-blast type of interrupter is used exclusively for 15- and 34.5-kv ratings, because it was found to be better suited for the much higher interrupting and current-carrying requirements.[6] Circuit breakers with cross-blast interrupters require only a single set of contacts, are simple in construction, and are easily accessible for inspection. They are available in up to 4,000- and 5,000-ampere current ratings, and are capable of interrupting in excess of 100,-

---

Paper 49-94, recommended by the AIEE switchgear committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted November 16, 1948; made available for printing December 20, 1948.

B. P. Baker and E. Frisch are with the Westinghouse Electric Corporation, East Pittsburgh, Pa.

The development of the circuit breaker described in this paper was undertaken as a natural part of the development of metal-clad equipment to meet the requirements of A. M. de Bellis, Consolidated Edison Company of New York.

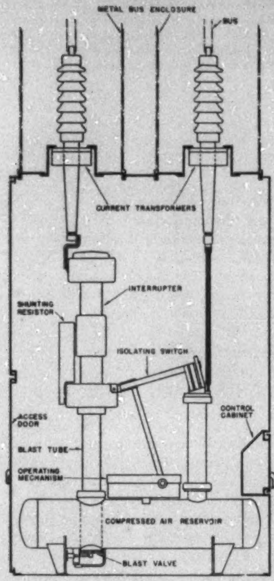

Figure 1 (left). Sectional view showing a 69-kv, 2,000-ampere, 3,500,000-kva compressed-air circuit breaker mounted in an outdoor dust-proof enclosure

000 amperes at 15 kv without the use of a shunting resistor. Some experience, however, has been gained in this country with the orifice type of circuit breakers for high-voltage outdoor service.[7,8] The results generally have been satisfactory, but because of the excellent performance of highly-developed dead-tank oil circuit breakers, their use has been confined to a few trial applications.

Summarizing, compressed-air circuit breakers of the orifice type are used in Europe for indoor low-voltage service as well as for outdoor high-voltage service. In this country, we have cross-blast compressed-air circuit breakers indoors and oil circuit breakers outdoors, with the possibility of the orifice-type compressed-air circuit breaker entering the outdoor field. If higher voltages move indoors, it is probable that the requirements for current-carrying and interrupting capacities would favor the orifice type of interrupter for these voltages.

The Circuit Breaker and Its Enclosure

Figure 1 shows a schematic drawing of a pole unit of a recently-developed 69-kv 3,500,000-kva 2,000-ampere orifice-type compressed-air circuit breaker, mounted in a steel enclosure for outdoor service. The enclosure, containing separate compartments for each of the three poles, includes six condenser bushings with current transformers. Although the upper ends of the bushings are porcelain clad, they will not be exposed directly to the weather, but will extend into the bus enclosure, which is shown attached to the roof of the circuit breaker enclosure. Each compartment is provided with a door and ventilating louvers. The doors are sealed with rubber to exclude rain and dust. The louvers are provided with dust filters.

The center compartment of the circuit breaker enclosure has a built-in control cabinet in which is located the control panel, auxiliary switches, pressure switches, gauges, control valves, and various interlocking elements. The interlocking system prevents access to the circuit breaker compartments without first tripping the circuit breaker and opening the disconnect switches.

Figure 2 shows a single pole unit as shown schematically in the enclosure of Figure 1. Each pole consists of an air reservoir on which is mounted the other elements of the circuit breaker. The breaker, therefore, is not dependent upon the metal enclosure for support. The only points of attachment are at the base and at the power connections to the condenser bushings.

The blast valve is mounted in a tube extending through the reservoir. It is of the differential-area air-actuated type, easily removable from the under side of the reservoir without disturbing the superstructure.

Above the blast valve is a heavy Micarta blast tube. This tube also serves as the support for the interrupter and forms the insulation to ground.

The contacts of the interrupter are normally biased to the closed position by springs except during the interrupting period, and, therefore, a series isolating switch must be provided. The lower end of the interrupter forms the hinge support for the isolating switch. The stationary contact of the isolating switch is supported by a second Micarta tube mounted at the opposite end of the air reservoir. The isolating switches of the three poles are gang-operated by a single pneumatic mechanism which is mounted on the air reservoir of the middle pole. The three poles, therefore, are tied together mechanically by the isolating switch shaft, pneumatically by a common control for opening the blast valves, and electrically through a single control system.

Method of Circuit-Breaker Operation

A schematic diagram of a complete 3-pole circuit breaker with its pneumatic system is shown in Figure 3. When the blast valve opens, compressed air at 200 to 250 pounds per square inch is admitted through the blast tube and the lower exhaust chamber to the space surrounding the moving-contact assembly. This assembly consists of two pairs of moving and stationary contacts connected in series. The moving contacts normally are biased toward the closed position by means of heavy contact-closing springs. As a result of the pressure exerted upon the lower moving contact by the compressed air, the contact opens, thereby interrupting the circuit except for the residual current which flows through a shunting resistor connected across the lower pair of contacts. This resistor consists of a number of cast grids with mica spacers, clamped together and mounted in an insulating tube. The upper contacts open in slightly less than one cycle after the opening of the lower contacts, as a result of the throttling action of the narrow space between the upper contact holder and the upper insulating tube. Because of this delay, the fault current is transferred to the shunting

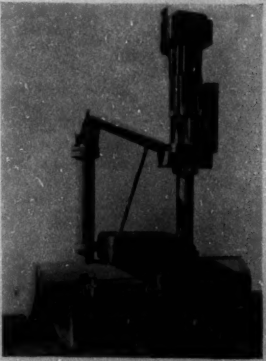

Figure 2 (right). Single pole unit of a 69-kv, 2,000-ampere, 3,500,000-kva compressed-air circuit breaker set up for interrupting tests in East Pittsburgh high power laboratory

Figure 4. Pneumatic mechanism for gang operation of the three isolating switches

Cover removed

resistor and greatly reduced before the upper contacts open.

When the moving contacts open, the orifice openings in the stationary contacts are uncovered. The high-pressure air forces the established arc toward the center of the opening and completely envelopes it with a high-velocity turbulent flow which sweeps the ionized gases through the hollow stationary contacts to the lower and upper exhaust chambers. Here, the gas is cooled before it is exhausted slowly to the surrounding atmosphere through mufflers. These restrictions to the free flow of the exhaust gases reduce noise and external demonstration to a minimum.

The three isolating switches are gang-operated by a single pneumatic mechanism through a rotating shaft and three wood Micarta rods. The shaft is connected to the piston of the mechanism through a rack and gear transmission, permitting 180 degree rotation. This places the mechanism in complete toggle in both the open and the closed position of the isolating switches. The movement of the piston is controlled by a sliding, cylindrical control valve on top of the mechanism cylinder. High-pressure air is admitted to either end of the valve as required, and causes movement of the valve to the corresponding operating position. In this position, the valve uncovers a port which admits high-pressure air to one side of the piston, resulting in either closing or opening the isolating switches.

At the same time, a second port is uncovered, through which the air on the other side of the piston is discharged to the atmosphere. This is required in order to obtain rapid opening of the isolating switches when they are being closed on a fault resulting in immediate tripping. The diameter of the "opening" end of the valve piston is slightly larger than the diameter of the "closing" end. Therefore, if control air for opening and closing of the isolating switch is applied to the mechanism at the same time, preference will be given to the opening operation. The circuit breaker, therefore, is pneumatically trip free.

High-pressure air for opening the isolating switches is taken from the blast tube on the middle pole. The air passes through an interlocking valve, connected pneumatically to the blast tubes of the two other poles. By this means, the high-pressure air is prevented from reaching the operating mechanism and opening the isolating switches until all blast valves are open and pressure is available in the interrupters for arc extinction. In addition, the blast valves are prevented by the electrical control from reclosing until the isolating switches are opened sufficiently to remove the voltage across the interrupters.

The operation of the three blast valves is controlled by a single electropneumatic tripping valve, mounted on the middle reservoir. When the tripping coil is de-energized, the tripping valve admits high-pressure air from the reservoirs to the underside of the blast valves, forcing them tightly against their seats. When the tripping magnet is energized, the tripping valve shuts off the high-pressure air supply and discharges the air under the blast valves, which then open by the air pressure on a portion of the upper side of the blast valves. The circuit breaker is closed by energizing the electropneumatic closing valve, which admits high-pressure air to the operating mechanism and closes the isolating switches.

The design of the operating mechanism is illustrated in Figure 4, which shows the mechanism with the cover removed. The two shock absorbers, shown in this illustration, serve to slow the speed of the isolating switches in the latter part of their travel in both closing and opening directions to lessen the shock of operation.

The Interrupter

The interrupter consists of two copper-alloy stationary contact members which are bolted to the upper and lower exhaust chambers, and a self-contained moving-contact assembly which is mounted in a centrally-located contact housing. The exhaust chambers with the stationary contacts, the contact housing with the moving-contact assembly and two insulating tubes used as spacing members, are clamped together by four spring-loaded, wood Micarta tie rods. The shop assembly of the interrupter, therefore, is extremely simple, a fact which

Figure 5. Exploded view of complete interrupter

Except for the removable contact assembly, all interrupter parts are clamped together by the four wood Micarta tie rods will be evident from examination of Figure 5, which shows an exploded view of all interrupter parts.

The moving-contact assembly, shown on top of the contact housing in the exploded view, is a self-contained unit consisting of a contact-support casting in which are mounted the two sets of moving main and arcing contacts with their heavy stainless-steel closing springs. The main contacts consist of a cluster of contact segments, each with two contact springs, mounted in a contact holder around the silver-tungsten-tipped arcing contact. With the contact assembly in place in the contact housing, the closing springs, acting on the contact holders, force the ends of the contact segments and the arcing contacts against the flat ends of the hollow stationary contacts, and cover the orifices in these contacts. The current is carried from the upper to the lower contacts on a stationary copper-alloy contact sleeve on which the contact segments slide.

When high-pressure air enters the contact housing from the blast valve, the moving-contact holders, acting as pistons, are forced away from the stationary contacts, carrying with them the contact segments and the arcing contacts. The latter remain closed and carry the fault current momentarily until the contact segments have moved a fraction of an inch, thus preventing arcing on the current-carrying surfaces of the contacts. The flange of the upper contact holder extends into the lower end of the insulating tube when the contacts are closed. The narrow space between the flange and the tube throttles the flow of high-pressure air to the space around the upper stationary contact, and delays the establishment in this space of sufficient pressure to open the contacts. The throttling effect is adjusted so as to delay the opening of the upper contacts till slightly less than a cycle after the opening of the lower contacts. The throttle opening is enlarged as soon as there is movement of the contact holder, thus removing all restrictions to free air flow, required for interruption. This delayed contact opening is an important feature which has made it possible to design the contacts for maximum efficiency. The lower set of contacts, which opens first, must be capable of interrupting very high currents, but the rate of rise and the magnitude of the restored voltage is low because of the shunting resistor. For this duty, a small contact separation and a large orifice opening are most effective. The upper contacts will not be subjected to a high-current arc, but must handle highly inductive and capacitive loads such as transformer-magnetizing currents and cable-charging currents, both of which may involve considerable overvoltage. For this interrupting duty, a smaller orifice opening and considerably more contact separation give the best results.

The contacts can be inspected by removing an inspection cover from the contact housing and by forcing the contacts to the full-open position by means of a special contact withdrawing tool. This brings both the moving and stationary contacts into full view. For closer examination, or for replacement of contact parts, the complete moving-contact assembly can be removed from the interrupter, as shown in the exploded view.

Test Results

Table I shows the results of several series of consecutive tests. Nineteen of these tests were made at 60 kv with currents ranging from 220 amperes to 22,500 amperes. Seventeen were at 50 kv with currents ranging from 180 amperes to 10,400 amperes. Seven were made at 44 kv with currents ranging from 11,700 amperes to 37,500 amperes. All tests were on a single-phase basis with full voltage across the interrupter. The interrupter consisted of two sets of contacts in series, one shunted and the other unshunted. The interrupting effort, therefore, is made in two steps. The first step covers the period from application of trip-coil voltage until the arc is interrupted on the lower or shunted set of contacts. Column 4 of Table I gives the time required for this step, which is a minimum of 1.5 cycles and a maximum of 2.4 cycles. The second step covers the interruption of resistor current on the upper unshunted contacts. Column 5 of Table I gives the total circuit breaker time from the application of trip-coil voltage to the extinction of the resistor current, the minimum time being 2.6 cycles and the maximum

4 cycles. The tests at 44 and 50 kv were made with a reservoir pressure of 230 pounds per square inch; the tests at 60 kv, with 200 pounds per square inch pressure. The tests were made at pressures somewhat below the normal operating pressure of 250 pounds per square inch to check the interrupting ability under conditions corresponding to a second operation with the reservoir sealed off from the air supply system.

Figure 6 shows magnetic oscillograms of two high-current interruptions at 44 kv. One represents the capacity of the laboratory on a symmetrical current basis of 22,400 rms amperes. The other represents the full capacity on an unsymmetrical current basis giving 37,500 rms amperes. Figure 7 shows magnetic oscillograms of two high-current interruptions at 60 kv. Both were at the full capacity of the laboratory, one being symmetrical and the other unsymmetrical.

* Magnetic oscillograms of these tests are shown in Figure 8.

Table II shows a series of 20 consecutive interrupting tests, all of which were made with 60 kv across a single interrupter. These tests were made to simulate conditions when opening a circuit consisting of an unloaded cable. Except for the normal impedance of the power circuit, the current for this group of tests was limited to 45, 90, and 180 amperes respectively by the use of a capacitor load in series with approximately 300 ohms of resistance. All tests were made with a reservoir pressure of 200 pounds per square inch. Column 4 of Table II shows the total circuit breaker time for interruption, from the application of trip coil voltage to the extinction of the residual current through the circuit breaker resistor. The times are very consistent, being maximum 3 cycles and minimum 2.5 cycles. The oscillogram of *test 2-89576*, which is given in Figure 8, records the only reignition observed during this entire set of tests. This reignition occurred before the upper contacts were fully separated, and, as is apparent, the voltage reached before breakdown was less than the voltage on the following half-cycle, which seems to have been influenced very little by the reignition. Column 6 of Table II is a tabulation of the maximum instantaneous values of voltage reached during the interruptions. The second oscillogram in Figure 8 is typical, and shows an instantaneous value of 161 kv. The maximum voltage observed during the series of tests was 168 kv.

It should be noted that the tests shown in Tables I and II were made on the interrupter as finally developed, but mounted on an experimental reservoir without a series isolating switch.

Table III shows a series of consecutive tests made on the complete circuit breaker unit shown in Figure 2. Eleven of these tests were made at 44 kv, 220 pounds per square inch reservoir pressure, single phase, on a close-opening basis. The

Refer to Table I

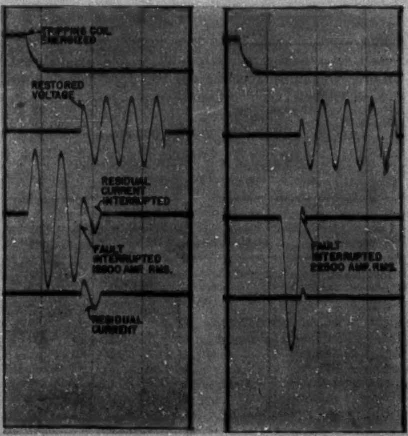

Figure 7 (right). Magnetic oscillogram showing single-phase current interruption of 12,800 and 22,500 rms amperes at 60 kv in 2.7 and 2.6 cycles respectively

Refer to Table I

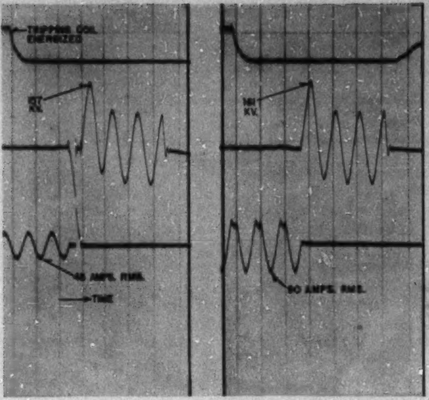

Figure 8. Magnetic oscillogram showing single-phase charging-current interruption of 45 and 90 rms amperes at 60 kv in 3.0 and 2.8 cycles respectively

Refer to Table II

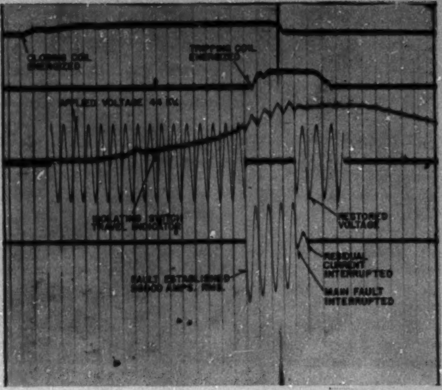

Figure 9. Magnetic oscillogram showing single-phase operation closing 26,000 rms amperes and opening 21,400 rms amperes

Fault duration 5 cycles including relay time. Refer to Table III

faults were closed on the isolating switch and opened in the interrupter.

The currents closed varied from 750 to 26,000 rms amperes. The currents opened varied from 710 to 21,400 rms amperes.

The circuit breaker was tripped by a current transformer and relay. When a high-speed relay was used, the total fault time, including relay and circuit breaker time, did not exceed 5 cycles.

Figure 9 shows the magnetic oscillogram of *test 2-91678*, when a current of 21,400 rms amperes was interrupted. At the conclusion of these tests, the interrupting contacts and isolating switch contacts were in excellent condition. Without cleaning or touching up, they successfully passed their momentary and 4-second tests at 57,500 and 36,500 rms amperes respectively. In order to demonstrate their ability to perform heavier-duty service, they were, without cleaning or touching-up subjected to momentary and 4-second tests of 100,000 and 59,400 rms amperes respectively, and were found to be in good operating condition at the conclusion of these tests. This circuit breaker also has passed the commercial impulse test of 350 kv, and a temperature test at 2000 amperes, 60 cycles, with a rise of 25.5 degrees centigrade.

Conclusions

Test results, simplicity, accessibility, safety, and ease of contact removal seem to indicate that this circuit breaker may find a field of usefulness for indoor service. When placed in a metal enclosure and equipped with condenser bushings, as shown in Figure 1, it appears to be competitive with oil circuit breakers, especially when used in combination with metal-clad bus structures. The circuit breakers, when equipped with porcelain weather casings, may be acceptable for general outdoor service, especially where current transformers and potential devices are not required.

Table III. 69-Kv 3,500,000-Kva 2,000 Ampere Compressed-Air Circuit Breakers

Single-Phase Close–Opening Tests, Reservoir Air Pressure, 200 Pounds per Square Inch, Circuit Breaker Tripped from Current Transformer Through Relay

Test Number	Voltage Across Single Pole, Kv	Rms Amperes, Closed	Rms Amperes, Interrupted	Duration of Fault Cycles	
2-91667	33	520	450	12	
68	44	750	710	12	
69	44	1,240	1,180	11.5	
70	44	2,000	Ampere setting	No oscillogram record	
71	44	2,100	2,200	5.0	
72	44	2,330	1,940	5.0	High-speed relay used in tripping circuit
73	44	4,000	3,900	5.0	
74	44	8,700	6,700	5.0	
75	44	9,600	9,200	5.0	
76	44	13,400	11,700	4.5

Discussion

P. L. Taylor (Allis-Chalmers Manufacturing Company, Boston, Mass.): We feel that the authors have done an excellent and thorough job of selecting, combining, and adapting the best principles developed in European air-blast circuit breaker practice, to achieve a 69-kv high interrupting capacity orifice-type indoor air blast circuit breaker design, arranged in an outdoor cubicle for application in congested residential areas.

The comprehensive series of tests reported on this circuit breaker further confirm evidence previously accumulated both in Europe and in the United States that the axial-blast contact arrangement of the orifice type circuit breaker is capable of excellent performance when interrupting currents of considerable magnitude. Western Europe is developing circuit breakers capable of interrupting 100,000 amperes and 3,000,000 kva.

The author's reference[8] on a 34.5-kv indoor station type air-blast circuit breaker, has been offered by them in substantiation of their statement that the cross-blast type of interrupter is used exclusively in the United States for 15- and 34-kv service because it is better suited for the higher interrupting and current carrying requirements.

To prevent misunderstanding, we should point out that the Jansson circuit breaker does not employ the cross-blast type of interrupter. It is provided with the contact arrangement usually associated with cross-blast circuit breakers, but the interrupting structure is of the orifice type. Thus it combines the advantages of both in what Mr. Jansson has called a cross-axial blast circuit breaker.

No doubt the authors have data to indicate the adequacy of 69-kv Micarta tubular insulation under the moisture condensation conditions encountered in outdoor metal-clad arrangements or they may have made special provisions to adequately control or eliminate the effects of such condensation. In either case the information would be of considerable interest to all.

Viewed fairly, this circuit breaker appears to fulfill many, if not most, of the special requirements for a high-voltage high interrupting capacity oilless circuit breaker for application in congested residential areas.

R. B. Shores (General Electric Company, Philadelphia, Pa.): The arrangement of an interrupter element and an isolator switch mounted on the unit's air storage tank has been used in several European air blast circuit breaker designs and results in a compact unit not requiring a separate framework to maintain alignment of the circuit breaker parts. Also, the rack and pinion type of operating mechanism with an overcenter arrangement to avoid springs and latches is simple, and has been in satisfactory use for some time on one American design of large indoor circuit breaker. However, this particular indoor 69-kv arrangement does not seem to lend itself to the use of a separating metallic barrier between the primary circuit elements of the circuit breaker and the mechanism. The cross-section of the circuit breaker in its enclosure indicates that inspection or maintenance of the mechanism must be performed by entering the primary compartment. It would be interesting to find out the user's reaction to the necessity of entering the primary compartment for any inspection of the circuit breaker mechanism, as to date most American circuit breakers have permitted the inspection or maintenance of the principle operating mechanism of either indoor or outdoor circuit breakers without necessarily getting dangerously close to primary circuit elements.

Reference in the paper has been made to electrical, mechanical, and pneumatic interlocks, and it would be inferred that these types back-up each other to give overlapping protection. However, it would appear from the schematic diagram that these interlocks are not successive stages against misoperation of some function of the circuit breaker, but are used independently depending on the convenience of each for the function to be interlocked. Is this correct, or is the failure for example of the pneumatic interlocking of the interrupting contacts, or of the blast valve, backed up by mechanical interlocking?

In considering the detail arrangements of the circuit breaker parts, it would appear that the location of the blast valve not only entails difficulties in inspection or maintenance, but might even act as a sump for the tank. Indoor compressed air circuit breaker tanks are normally provided with a blow-off valve as it is recognized that water may get into these tanks, especially during the initial placing in service of the circuit breakers. Is the blast valve inspection cover at the lowest point of the tank, and, if it is, has some means been provided to blow out the resulting sump?

Robert H. Nau (University of Illinois, Urbana, Ill.): According to a long established custom of the AIEE, the authors of a technical paper are more or less obligated to answer to the best of their ability all of the questions posed by an interested reviewer, providing he, the reviewer, has not by his investigative ability uncovered something which is considered confidential. Hence, I will assure you before I begin firing my questions that I have not been more intimate with this circuit breaker than having observed it casually and having studied the authors' present paper. Some of my questions may appear to have been answered by the text of the paper. In such cases I point out that the explanations have not been complete enough, and I would like for the authors to cover these particulars in greater detail. Please note that I have studied your paper forwards and backwards. Further, I have had considerable experience with contemporary circuit breakers, and hence know where to look for trouble points.

The abundance of test data on the new 69-kv compressed air circuit breaker substantiate its rating to interrupt short-circuit currents. However, you will note the restrikes or reignitions on each of the first oscillograms of each of Figures 6 and 8. Also, you will note that the second oscillogram of each of Figures 6 and 7 might be considered fortuitously lucky shots, catching the brunt on the little half-cycle of a highly asymmetrical current wave. There has been considerable contention concerning the validity of using oscillographic data for properly rating a circuit breaker when the arc is being quenched during the little half-cycle of a highly asymmetrical current wave. I refer you to my detailed closing discussion of a paper published in 1940.[1] I do not criticize the circuit breaker, but merely emphasize that these several phenomena indicate that the circuit breaker was operating at its optimum or maximum rating during these tests.

The remaining part of my discussion will deal more generally with the mechanical aspects of the 69-kv compressed-air circuit breaker. It is gratifying to see the rack mechanism put to work again, here as the link between the pneumatic operator and the disconnect or isolating switch. However, I ask the authors for the diameter of the associated gear and, also, the depth, breadth, and thickness of the teeth of the gear. Further, have you had or do you anticipate any alarming experience as concerns the teeth of this gear in shear?

The massive interrupter and its associated high-speed disconnect or isolating switch form an impressive podium when balanced or supported by the single Micarta tube, especially when there is no accompanying bracing. There is the thrust of the blast of air and the whipping action of the isolating switch for each operation. One would suspect that considerable stress would be encountered for each operation!

For circuit breakers of 2,000 to 5,000 amperes continuous current ratings the isolating switch becomes, by necessity, quite a mass in cantilever. Even with bumpers or shock absorbers incorporated in the pneumatic operator, I would suspect some difficulties especially if the isolating switch is given snappy action.

The main and arcing contact assembly intrigue me very much. Since the exploded view, Figure 5, is almost obscure, I would like to have a close-up or a detailed sketch that we may comprehend the construction. How much does each pair of main and arcing contacts weigh? How do you combat contact chatter and mushrooming during repetitive operation?

We are led to believe that the contacts may be inspected by removing the cover-plate window as shown in Figure 2, providing the mechanic has a specially-built contact retracting and revolving tool. However, it seems that a fairly large boom would be required to aid the mechanics in removing the massive interrupter podium from the supporting compressed air reservoir when more detailed inspection or repairs are necessary.

Please give us the following named dimensions:

1. The diameter and length of the compressed air tank.
2. The length and diametrical dimensions of the main supporting Micarta tube.
3. The height of the interrupter podium, from the top of the compressed air reservoir to the top of the upper muffler.

In the section Method of Circuit Breaker Operation, I presume the authors mean by "the throttling action of the narrow space between the upper contact holder and the upper insulating tube" that a slightly longer time is required for the pressure to build up in the more distant end of the tube before the second contact will open. The timed sequence of the opening of the two contacts is of some consequence! Besides taking design precautions in dimensioning the space between the upper contact and the insulating tube, how much have you considered varying the strength of the upper spring in relation to that of the lower spring? What are the magnitudes of these spring loads when the contacts are in closed position? How do you co-ordinate the dimensioning of the throttling space and spring loads when going from the 2,000 to the 5,000 ampere circuit breaker?

The questions which I have posed are more than academic, in fact, the operator will find them quite real. Hence, I ask, how well does the circuit breaker hang together, and how do the main contacts perform after a life test of 20,000 closing operations at no-load, or even after 5,000 operations?

As to the general trend in the design of compressed-air circuit breakers, I should like to emphasize that the European axial-blast or orifice-type circuit breaker has set the style pattern. It has been found expedient to resort to the famed cross-blast circuit breaker only when going to the lower voltages of the high-voltage classes where short-circuit currents of excessive values are encountered. I prognosticate that the axial-blast or orifice type of compressed air circuit breaker will be made to surpass even the cross-blast circuit breaker when our Westinghouse development engineers have completely co-ordinated the action of the paralleling resistor with the series and shunt orifices. The operation is most promising, and I feel that only a short time will pass before the voltage and kilovolt-ampere ratings will be extended to the highest transmission values. I suspect the orifice type of compressed-air circuit breakers will crowd all of the oil types.

REFERENCE

1. MAGNETIC "DE-ION" AIR BREAKER FOR 2,500–5,000 VOLTS, L. R. Ludwig, R. H. Nau. *Electrical Engineering* (*AIEE Transactions*), volume 59, September 1940, pages 519–22.

W. F. Skeats (General Electric Company, Philadelphia, Pa.): The authors are to be congratulated upon developing a 69-kv circuit breaker for operation in a metal enclosure. Certain questions present themselves, however, and I should like to address them to the authors.

1. It would be interesting to know whether the unit has been subjected to close or close-open duty within a metal enclosure such as is to be used in the installation. While such ionization as is produced by arcing at the isolating switch on closing is dissipated readily in the open air, experience has shown, on occasion, that it may be considerably more dangerous within a relatively tight enclosure.

2. The creepage distance across the Herkolite tube surrounding the upper break appears to be of the order of 12 inches both inside and outside. This insulation carries the full burden of maintaining an open circuit until the series isolating switch has achieved a substantial contact separation. According to Figure 9, this interval is about 20 cycles. Has this break been subjected to insulation tests, or is a somewhat reduced insulation for this period considered acceptable?

3. It appears from the oscillogram of Figure 9 that an interval of the order of 12 to 15 cycles elapses from the time the blast valve is opened for the interruption to the time when the isolating switch has built up a contact separation equal to that at which the arc strikes on closing a 44-kv circuit. Is air being lost through the blast valve during all of this period, or is there some provision for reducing its flow?

4. The contacts appear to perform in a rather unusual manner. It would be interesting to have more details of the arrangement for accomplishing the various functions in the proper sequence.

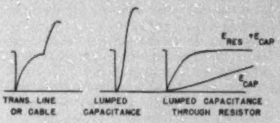

Figure 1. Voltages following restrike

5. The authors appear to have convinced themselves that a resistor is a reliable adjunct to a circuit breaker, and having done so, have built a resistor to pass quite substantial currents. Just what value of resistance is to be used is not quite clear, as Figure 6 shows a resistance current of about 3,800 amperes at 44 kv, corresponding to a value between 11 and 12 ohms, while Figure 7 shows a current of about 3,500 amperes at 60 kv, corresponding to a value of 17 ohms. Residual currents commonly used in recent practice have for the most part been about 10 per cent of the continuous current of the circuit breaker or less, but the values stated above are as high as the short-circuit current through 20 miles of transmission line at the rated voltage of the circuit breaker. The question may very well be raised whether currents of this magnitude are properly referred to as "residual." For the purpose of determining interrupting time, they should certainly be included.

6. The authors have used a peculiar circuit in their tests for interruption of cable charging current, in that a resistance of 300 ohms was inserted in series with the capacitance. This resistance corresponds reasonably well with the surge impedance of transmission lines, but since the authors particularly mention cable, which has a very much lower surge impedance, that fact presumably had nothing to do with the choice of value. Even with a resistance value corresponding to the surge impedance, however, the oscillations and overshoot associated normally with a restrike on either a lumped capacitance circuit, a transmission line, or a cable are substantially eliminated as indicated in Figure 1 of the discussion. The progressive build-up of voltage is, therefore, eliminated and the overvoltages greatly reduced. Performance on such a circuit can hardly be taken as a reliable indication of performance on field circuits.

A. M. de Bellis (Consolidated Edison Company of New York, Inc., New York, N. Y.): The 69-kv system which is planned for the East River Station 60-cycle development, of the Consolidated Edison Company is the first use of this voltage in New York City. Present-day conditions and particularly the increased cost of building structures and of switching equipment for the large kilovolt-ampere ratings have made it necessary to decentralize the switching galleries of the generating stations, by transmitting bulk power at high voltage to various distributing substations located at the load areas.

In distributing the large blocks of power which we have to handle in New York, it has become necessary to step up the generator voltage to 69 kv and then transform it back again to 13 kv at the area substations, even though the distance between the generating station and the substation may be short. With this arrangement some 69-kv switching equipment is required at the generating station.

In regard to the high-voltage circuit breakers it was our desire to avoid the use of oil and to adapt this equipment to newly designed 69-kv outdoor metalclad bus and disconnect switchgear equipment. We feel that the designers of the new air-blast circuit breaker, described in the paper, have accomplished the desired results in this respect. The design of this circuit breaker is unique since the usual outdoor circuit breaker of this voltage does not have a housing around it. This arrangement fits in very well with the metalclad isolated-phase type of bus construction and also permits the use of bushing current transformers over each circuit breaker terminal.

The circuit breaker designers are to be complimented for their courage in undertaking the construction of an air-blast circuit breaker for operation at 69 kv, and at the highest interrupting kilovolt-ampere rating now recognized in the new ASA Standards for this voltage class. The test results described in the paper show that the interrupter is efficient and is apparently capable of even greater interrupting capacity than its rated 3,500,000 kva. It would be interesting to see tests carried to higher levels of kilovolt-amperes to learn the actual interrupting limits of the circuit breaker.

Since this circuit breaker is to be used on a 69-kv cable system, we were particularly interested in its ability to interrupt cable charging currents. The test results showing only one "restrike" in 20 tests are reassuring so far as the possibility of imposing overvoltage on the cables, due to switching, is concerned.

H. V. Nye (Allis-Chalmers Manufacturing Company, Milwaukee, Wis.): The circuit breaker described in this paper differs from orifice-type circuit breakers presented previously to the Institute, largely in the use of a separate orifice and contact for introducing the series resistor. The use of a separate contact for this specific purpose may have some advantages, but I wish to point out that it has one distinct disadvantage. It adds approximately one second to the possible minimum arcing time obtainable. A study of Table I will illustrate this fact. The main current interrupting time varies from 1.5 cycles to 2.4 cycles depending on the load interrupted, but with a fixed time delay for the second orifice we find the total interrupting time runs from 2.6 to 4 cycles.

Previous air-blast circuit breakers have employed a probe in the arc path which serves to parallel the resistor with a portion of the arc and accomplish the purpose of the first orifice described by causing the portion of the arc paralleled to be extinguished leaving only the residual current through the resistor flowing. The residual current is then extinguished by the continued action of the air blast.

The advantage of this construction is that no mechanical timing is introduced for the transfer and it is accomplished as fast as the circuit conditions permit, usually in 1/2 to 1$^1/_2$ cycles. The extinction of the residual current then takes place very rapidly, in most cases only a fraction of a cycle. Consequently interruption in a total time of 1$^1/_2$ to 2 cycles are obtainable.

This may be of little importance so long as the operating time shown is acceptable, but indicates the ultimate possibility of shortening the operating time.

Other than above, the circuit breaker described by the paper seems to be well designed and the authors are to be complimented on presenting sufficient test data to give confidence in the circuit breaker rating.

The proposed outdoor construction with entrance bushings supported by an enclosure is interesting and helps solve the problem of bushing transformers.

In conclusion, the type of circuit breaker best adapted to American conditions, air blast, impulse, or ruptor types, will probably be determined largely through evaluation of the following factors, rather than by arcing times. These factors are: manufacturing cost; maintenance expense; and relative weight and space occupied.

This is due to the fact that adequately short arcing times are now possible with all three types of circuit breaker.

O. B. Vikoren (Philadelphia Electric Company, Philadelphia, Pa.): The authors are to be congratulated on their efforts to solve the problems confronting power companies which have to use increasingly higher voltages in congested metropolitan areas. We have in mind particularly the reduction of fire hazards, the totally-enclosed design of all high-voltage parts described, and the reduction in noise levels of this equipment. The paper indicates that no efforts have been spared to comply with the needs of the user in these respects. However, simplicity in design of switching equipment is generally a requirement, and although the authors appear to have tried to achieve this in the design of the 69-kv compressed air circuit breaker, the result leaves much to be desired. From the user's point of view it is believed that the compressed-air circuit breakers above 34.5 kv will have much wider acceptance in the industry if the mechanical parts of these circuit breakers, with respect to simplicity, would compare more favorably with those of oil circuit breakers. The authors could have explained in more detail their reasons why in the 69-kv, 3,500 megavolt-amperes compressed air circuit breaker a simple interrupter, without an external isolating switch, would not have been a suitable design. Visual inspection of the isolating switch does offer added insurance of safety, but this point can hardly carry much weight once the entire equipment is metal enclosed.

The 69-kv compressed-air circuit breaker with its many moving parts with precision tolerances can be expected to have higher maintenance costs than a switching device of equivalent rating, in which less precision work is required. It is recognized that the compressed-air circuit breaker is in the early stages of development and that many difficulties remain to be overcome. However, it is hoped that rapid progress will be made toward a design which will compete with established equipment in first cost, simplicity, and maintenance cost.

The authors might have emphasized earlier in the paper the fact that the compressed-air circuit breaker is suitable for outdoor installations in porcelain clad design. There may be many installations in which compressed-air circuit breakers are used in conjunction with transformers and similar equipment where the current transformer problem can be divorced from the circuit breaker entirely. In these cases there is often no need for the metal enclosure.

In general, the explanation of the operation of the circuit breaker is very thorough although it is unfortunate that the schematic diagram, Figure 3, is not clearer, since it does not convey the toggle action of the mechanism of the isolating switch, although it is indistinctly shown in Figure 4, a feature which is of extreme importance under through-fault conditions. In this connection it is believed that a few words about how the blast air passes the section of the air passage, which is shown as an exhaust port in Figure 3, would have been helpful.

From the test results it appears that the circuit breaker complies with the ASA requirements for speed with little or no margin. If this circuit breaker design is to be carried over into the 138-kv class and above, where three cycles interrupting time is required, it would be interesting to learn how the increased speed is expected to be obtained.

B. P. Baker and E. Frisch: It appears Mr. Taylor feels that the authors should not have used Mr. Jansson's paper as a reference for a cross-blast circuit breaker. If the reference has been misleading we wish to apologize. Mr. Jansson's paper shows very clearly that the heavy current carrying requirements are met by a contact structure quite similar to that used in the cross-blast circuit breaker. Also, the air blast is perpendicular to the motion of the contact as in the case of the cross-blast circuit breaker and since there has been no details shown on what Mr. Jansson calls the cross-axial blast we felt that any compromise design between the cross blast and axial blast would be more similar to the cross blast and could be classified as such. This appeared logical in view of the authors unsuccessful efforts to meet the heavy current requirements with a compromise design.

The use of Micarta insulation seemed justifiable on the basis of its satisfactory performance at 34.5 and 138 kv, where very liberal distances are provided, and when metal fittings at high potential are properly rounded and shielded. The condensation of moisture is precluded on the inner surfaces, by the use of predried air and on the outside surfaces by the application of heat and controlled ventilation.

We wish to point out to Mr. Shore that in addition to the conventional electrical interlocking between the closing and the trip circuit, the opening of the isolators pneumatically takes precedence over their closing. Also, unless blast air is available in all three interrupters, the isolators get no opening air. There is no mechanical interlock between the interrupters and the isolating switches.

The blast valves as located are quite accessible for inspection and maintenance. Removal of several bolts permits the entire valve and its associated parts to be removed as a subassembly. The reservoirs are provided with blow-off or drain valves located at the bottom, showing very indistinctly and almost covered by the air supply line, in Figure 2 of the paper. While the blast valve is removable from the bottom of the reservoir, it is actually located near the center of the reservoir, where it is impossible for water to get into it.

Mr. Skeats has questioned the ability of the circuit breaker to perform close or close-open duty when mounted in its metal enclosure. Apparently he feels that the ionization liberated may produce a breakdown to the surrounding, uninsulated grounded metal surfaces. At the time this paper was written the circuit breaker had not been tested in its metal enclosure. Since then tests have been made with the circuit breaker in its enclosure, and perhaps Mr. Skeats' question can best be answered by briefly describing the tests.

This series of 12 tests was made on a single-pole bus with 44 kv applied across the circuit breaker. The first ten consisted of five standard duty cycle tests, that is, a close-open–15 second–close-open with the circuit breaker reservoir charged to 250 pounds per square inch before the first close-open test and then sealed off from the air supply. The test results were as follows:

Numbers 1 and 2, 1,050 and 790 amperes crest cleared, 580 and 530 amperes rms opened.

Numbers 3 and 4, 5,000 and 5,300 amperes crest closed, 2,200 and 2,340 amperes rms opened.

Numbers 5 and 6, 9,600 and 18,700 amperes crest closed, and 4,050 and 7,400 amperes rms opened.

Numbers 7 and 8, 23,900 and 28,800 amperes crest closed, 13,700 and 13,700 amperes rms opened.

Numbers 9 and 10, 48,000 and 40,500 amperes crest closed, 18,900 and 18,700 amperes rms opened.

The maximum circuit breaker time including interrupting the residual current through the resistor was 5.6 cycles. The maximum duration of fault current was 7.9 cycles.

Two opening operations were made with the current completely asymmetrical and with anticipatory tripping of the circuit breaker to obtain two interruptions of 39,000 amperes rms. One test was made with the circuit breaker reservoir charged, to 250 pounds per square inch, the other at 210 pounds per square inch. At the conclusion of these tests the circuit breaker including the isolating switch seemed to be in excellent condition. No evidence of smoke or discoloration could be found on the walls of the metal enclosure adjacent to the isolating switch.

Mr. Skeats raises an excellent question regarding the flow of air from the time the blast valve is opened until the isolating switch is opened sufficiently far to withstand voltage. The air from the interrupters after having passed through the orifice is discharged into exhaust chambers as shown in Figure 3. The volume of these exhaust chambers is such that they receive gas from the orifices at acoustic velocities for several cycles, to provide ample time for arc extinction; after this time the back pressure in the exhaust chambers decreases the rate of flow until further use of gas is decreased to zero, except for extraneous leaks and that provide for slow escape through the muffled exhausts, from the exhaust chamber. The air consumption is, therefore, somewhat independent of the speed of the isolator switch operation.

Mr. Skeats' fourth question regarding the unusual manner of contact performance is a little difficult to understand. If he refers to the sequencing of interrupter contacts, I am afraid I cannot do much better than to refer to the third paragraph of the section under "The Interrupter." I may add that the "flange of the upper contact holder" is shown schematically in Figure 3 as the moving contact member which is biased upward by a spring in the section that is labeled "moving contact assembly." This member is shown in Figure 5. In referring to the lower end of the insulating tube, it may have been more nearly correct to say that insulating plate adjacent to the lower end of the insulating tube.

In Mr. Skeats' fifth question he feels that the authors have convinced themselves that "a resistor is a reliable adjunct to a circuit breaker." Personally I hope it is reliable. However, I have a very strong conviction that circuit breaker development engineers resort to the use of resistances as props when they are unable to find another practical solution With considerable chagrin I must confess that in this case, I could not find another way of making an orifice type of circuit breaker interrupt large values of current, at reasonable air pressure, and at high rates of rise of restored voltage. Under the conditions of many service applications and field tests, the use of resistance may not have been necessary. However, we felt that for this application we could not afford to take a chance.

Mr. Skeats questions the sufficiency of the tests shown in Table II, to prove the adequacy of the circuit breaker to interrupt cable charging current. The 300-ohm resistance used in series with the capacitor bank was placed there to protect the capacitors which were being worked considerably over their rating. If no restrikes were encountered it was believed that the voltage condition on the circuit breaker would not be affected appreciably providing some overvoltage was used to compensate for the small correction in power factor. For this reason 60 kv was used instead of 44 kv, the voltage at which the circuit breaker should normally be operated. Nevertheless we concede that Mr. Skeats has raised an excellent question and since the writing of this paper we have made a series of 30 tests at 44 kv in which no resistance was used in series with the capacitor bank. No restrikes at all were observed.

Mr. de Bellis has not asked any questions, nevertheless the authors wish to hereby acknowledge his very fine discussion and thank him for clarifying several points that have been in the minds of many of us.

Mr. Nye has ably pointed out the relative merits of the two methods for introducing series resistors. In self defense we can only add, that tests seemed to indicate that for 69 kv, the method we used was the only one which produced consistent successful results at high values of current. We agree that for high-speed interruption, 3 cycles or less as is required at very high voltage, this residual current persisting for another cycle will prolong the de-ionization across a flashed insulator which will in turn delay high-speed reclosures. Therefore, this method requires modification for high-voltage high-speed fast-reclosing circuit breakers; but again, in these cases, the magnitude of the current may not require the use of resistors.

Several discussors have evidenced interest regarding costs, maintenance expense, weights, and space occupied. Mr. Nye has pointed out that the general acceptance of the various types of circuit breakers will ultimately be dependent upon these factors. About all we can add, is that the manufacturing cost cannot be determined accurately until production volumes are known, and some standard is set up for applying accessories such as, current transformer, potential devices, mountings, and other applicational data. The same is true for weights and installation space requirements.

While the circuit breaker was designed for ease of inspection and maintenance, only time and experience will be able to determine maintenance expense.

Mr. Vikoren suggests that the authors could have explained in greater detail why an isolating switch external to the interrupter was used instead of building the isolating switch into the interrupter. Presumably Mr. Vikoren has in mind a 34.5-kv outdoor Westinghouse compressed air circuit breaker, which has been in service on their system in Philadelphia for several years. In that circuit breaker, the isolating gap is formed by simply elongating the interrupting gap. There, one line terminal is located vertically above the other and the entire circuit breaker forms a single vertical column. This type of structure seems desirable for outdoor porcelain-clad construction up to 115 or 138 kv. For a circuit breaker built into a metal enclosure which is equipped with two condenser roof bushings per phase, it seemed logical to use a horizontal isolating switch external to the interrupter as shown in Figure 1 of the paper. In this case the contacts of the isolator switch are in full view through glass windows in doors of the metal enclosure and very little additional space is required.

Mr. Vikoren inquires regarding the air flow shown in Figure 3. The arrows indicate that the flow is up through the blast tube, through bypasses in the lower exhaust chamber, through the space between the lower stationary contact members and the outside insulating wall, through the orifice and back through the lower stationary contact, through cored openings into the exhaust chamber. These cored openings may be seen in the far casting of Figure 5. In this figure they appear as supports for the stationary contact member or orifice.

This general type of construction can be carried to higher voltages such as 230 kv and obtain 3-cycle interruption from rise of trip coil current. It is accomplished by using a faster exhaust for the gas under the blast valve and by locating the blast valve near the interrupter with a minimum of space in the interrupter to be filled. To be sure, no time can be sacrificed for opening residual current through a resistor. However, at high voltages, and lower current, resistors should not be required.

Mr. Nau has raised a host of questions, a number of which have already been answered in my reply to other discussers. I regret that space allotted to our paper made it impossible to cover the circuit breaker in sufficient detail to meet with Mr. Nau's approval; although I doubt if the Institute is generally interested in many of these unimportant details, consequently I am hereby tendering Mr. Nau a cordial invitation to visit our factory if he wishes to obtain complete information on this circuit breaker.

Mr. Nau points out that the restrikes showing in Figures 6 and 8 indicate that the circuit breaker is operating near its maximum rating. We do not feel that this is the case, since these early unsuccessful attempts to interrupt the residual current are generally associated with the occurrence of a current zero at very short contact separation.

Mr. Nau feels that the tests shown in "the second oscillogram of each of Figures 6 and 7 might be considered fortuitously lucky shots, catching the brunt on the little half-cycle of a highly asymmetrical current wave." I believe that, had Mr. Nau looked more carefully at Table I he would not have drawn the above conclusion. *Test 2-87662* and *2-89617* referred to in Figures 6 and 7, show an extinction time for the main power are of 2.2 and 2.3 cycles respectively. *Test 2-89597* at very low current where the duty on the transfer contact is very light shows an interruption time of 1.5 cycles, and it is hard to conceive of this arc going out before the contacts part. Therefore, one must assume that the contacts part in at least 1.5 cycles.

Subtracting 1.5 from 2.2 and 2.3 leaves 0.7 and 0.8 cycles respectively as the arcing time for the tests shown in Figures 6 and 7. It is therefore, apparent that the contacts parted near the beginning of the large current loop and arced throughout its entirety which is certainly not fortuitous. Had the contacts parted just before the zero on which interruption occurred, I would agree heartily with Mr. Nau. The "brunt" was not caught on the little half cycle. On both tests the main power arc was interrupted before the little half-cycle.

The rack and gear have shown no evidence of distress in a life test consisting of several thousand operations, to be sure firm conclusions cannot be drawn without many breaker-years of experience.

Mr. Nau has asked several detailed questions regarding a 5,000-ampere contact. Such a contact has not been designed and consequently we are just as much in the dark as is Mr. Nau. I wish to assure Mr. Nau that we appreciate his interest in this paper even though space does not permit us to answer all of his questions in detail.

Equivalent Circuits for Power-Flow Studies

J. B. WARD
ASSOCIATE AIEE

PRESENT-DAY extensive interconnection between power systems complicates the analysis of steady-state network performance in the study of planning and operating problems. This complication of analysis is increasing continually with system expansion and additional interconnections. Network analyzer studies of power-flow conditions on large systems frequently require preliminary simplification and reduction of the network, because of limitations imposed by the number of analyzer circuits and generator units available.

In studies for determining the distribution of power flow over the lines of a system under various emergency operating conditions, or with proposed future developments, interconnections may have an important effect, particularly if two or more ties exist forming parallel paths through the adjoining system. The total interchange of power between separate companies usually is established by interchange contracts, but in order to determine the proper division of this power flow over several tie lines under various operating conditions, it may be necessary to set up the adjoining system or an equivalent circuit representation of it.

The problem of network reduction in power-flow studies is not related solely to inter-company ties. Some individual systems have grown to such an extent that the complete network of major lines, stations, and substations exceeds the capacity of the largest existing network analyzers. Even on smaller systems, simplification of the network by means of equivalent circuits can be employed advantageously, to speed up the progress of studies when interest is focused on a certain section.

This paper outlines briefly the existing commonly-used methods of network simplification, and presents additional methods for devising simple equivalent circuits which reproduce with reasonable accuracy the terminal performance of the actual system under conditions prevailing in the usual type of power-flow study. By these new methods an extensive power network, containing numerous loads and generators, is reduced to an equivalent circuit, as viewed from several selected terminals, requiring few network analyzer circuits and sources for its representation. Changes in generation or loads within the reduced system can be reproduced readily in the equivalent circuit. Although the methods are described, for the most part, in terms of the necessary tests and measurements on an a-c network analyzer set-up of the system to be reduced, derivation of the equivalent circuit analytically or by use of a d-c board is feasible. Based on constant-current representation of system loads and generation, the new methods will accomplish in many instances a greater simplification than previously-used equivalent circuits. Limitations of this treatment of loads and generation restrict application to load-flow studies, but in studies of this type acceptable accuracy can be attained.

Present Practice

Present practice in reducing the size of a network for analyzer power-flow studies is confined largely to two methods.

Method A. The network to be studied in detail is terminated at interconnecting points, and the adjacent system is represented by a load or generator attached at each of these terminals. Connections through the reduced system are omitted entirely, and an estimated tie line flow, based on system readings or previous studies, is reproduced in the stub loads and generators at the interconnection terminals. In system planning studies involving proposed future transmission development or location of new generating stations, the system changes are frequently so radical that it is not possible to predict, with sufficient accuracy, the loadings on the stub loads and generators used to represent multiple ties to an adjoining system.

Method B. The system to be simplified is replaced by an equivalent circuit in which the identity of the tie-line terminals and generator busses is retained, and the line network is represented by transfer impedances between these various busses. Equivalent load impedances appear as transfer impedances from each retained bus to neutral. The process of evolving this type of equivalent circuit from a network analyzer set-up of the system is outlined here for the dual purpose of providing a comparison with the new methods and of explaining certain steps in obtaining the new type of equivalent circuit.

A 1-line diagram of the system to be replaced by an equivalent circuit is represented in Figure 1. This diagram shows the loads, generators, and interconnection points, but the internal line connections are omitted. It is assumed that the system indicated in Figure 1 must be simplified before a detailed study of the adjoining network can be carried out. If tie-line terminals, generator busses, and neutral bus are to be retained, the branches of the resulting equivalent circuit, shown in Figure 2, can be obtained as follows.

Disconnect the generators and represent loads as constant impedances corresponding to the load real and reactive power at normal bus voltage. Connect an analyzer source from one of the terminals

---

Paper 49-96, recommended by the AIEE system engineering committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted October 4, 1948; made available for printing December 23, 1948.

J. B. Ward is with the School of Electrical Engineering at Purdue University, West Lafayette, Ind.

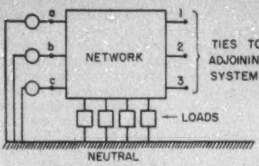

Figure 1. Typical system to be replaced by an equivalent circuit

to be retained, terminal 1 for example, to a new junction established at x, as shown in Figure 3. Connect zero-impedance metering circuits from junction x to all other terminals which are retained, including the neutral bus. Adjust the source at terminal 1 to an arbitrary value of voltage and read the current in each metering circuit. The impedance of the branch between terminals 1 and 2, in the equivalent circuit of Figure 2, is obtained by dividing the source voltage by the current in the metering circuit connected to terminal 2. It should be emphasized that all metering circuits are closed and carrying current simultaneously during this test. Similarly, the impedance of the equivalent branch between terminal 1 and neutral is the voltage at terminal 1 divided by the current in the metering circuit connected to neutral.

This process is repeated with the source connected successively to each retained terminal. At each step, all other terminals are connected to x through metering circuits. Thus, two measurements are obtained for each transfer impedance. The branches from the various generator and interconnection busses to neutral can be considered as equivalent loads. However, in the equivalent circuit derived in this way, the distinction between actual loads and line losses is lost.

The equivalent circuit, Figure 2, is connected at the proper points to the detailed set-up of the adjacent network. The desired internal generating schedule in the reduced system is established by adjusting sources connected to the generator busses of the equivalent circuit. If a different condition of loads is required in the reduced network, it is necessary to measure a new set of transfer impedances from the various terminals to the neutral bus. The transfer impedances, representing line connections between generator and interconnection busses, are modified only slightly by the presence of load impedances.

Certain branches of the resulting equivalent circuit are sometimes of such high impedance that they can be omitted entirely, but in general the number of branches is equal to $n(n-1)/2$, where n is the total number of terminals retained. The procedure just described is equivalent to applying star–mesh transformations to remove successively all busses except generator busses, tie-line busses, and neutral bus. The approximation of loads as constant impedances is required.

New Equivalent-Circuit Representation

The basis for the new equivalent circuit representation presented herein is the treatment of generation and loads, in the network being reduced, as constant-current quantities. By means of this approach, the internal generator busses as well as load busses in the reduced system can be eliminated, and the identity of only the tie-line terminals retained. The effects of suppressed generation and load are reproduced by an equivalent generator or load at each tie-line terminal, and the actual network of line connections is replaced by an equivalent mesh network interconnecting these terminals. The equivalent circuit of this type for the system of Figure 1 is shown in Figure 4. In principle the methods are rigorous for a hypothetical network in which all loads and sources are fixed impressed currents. The analysis of such a system is outlined in Appendix I, and, in the following paragraphs, the methods are adapted to the practical determination of simplified equivalent circuits for sections of power-system networks. Some of the important assumptions and approximations involved in this adaptation are listed briefly:

1. It is assumed that system loads can be considered as constant-current quantities. Usually loads are treated as constant impedances in analytical solutions of power-flow problems, and as constant-power loads in network analyzer studies. Differences in the three viewpoints become of major importance only under extreme voltage variations, as may occur during short circuits, for example.

2. Generators are usually held to a fixed power and voltage schedule, except for certain regulating machines. Reactive power generation may vary appreciably, but, as a rule, large blocks of reactive power cannot be transmitted economically over long distances. Furthermore, a large proportion of system studies are made at peak-load conditions, with generators operating at or near their maximum excitation. Hence, limited variation of power, reactive power, and voltage corresponds essentially to constant-current loading, in magnitude at least, on generators.

3. Angular displacements between bus voltages in a system usually are not large. Initial angles between various load and generator busses can be taken into account accurately, and then the assumption can be made that effects of subsequent variations in these angles can be neglected.

4. Synchronous condensers, static capacitors, and line charging capacitance can be treated as separate sources of reactive power or combined with nearby loads and generation.

5. Although the derivation of the equivalent circuit is based on the constant-current approach, it is assumed that the equivalent sources and loads, once determined, can be held at a fixed power schedule, for convenience in manipulation during studies.

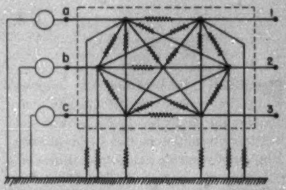

Figure 2. Equivalent circuit obtained by method B for the typical system of Figure 1

6. Initially, transformer turn ratios are assumed to be the same as ratios of the nominal voltages of the sections connected to the respective windings. Methods of handling transformer tap settings which result in other than nominal ratios are discussed in a later section.

7. It is assumed that, when a section of a power system is to be replaced by an equivalent circuit, detailed information on the performance of this section, with various line outages, for example, is not of immediate interest. Rather, the effect of this section during detailed study of the adjoining network is desired.

Determination of the Equivalent Line Network

After the section of the system to be reduced and the interconnecting terminals are decided upon, this section is set up in detail on a network analyzer, with all loads, generators, and capacitors open. The transfer impedances between the terminals to be retained are measured in the manner described under method B in "Present Practice," with the exception that, in the present method, only the points of interconnection are retained.

Equivalent Generators and Loads: Method I

Regardless of the number of internal busses suppressed in the reduced network, an equivalent generator and load can be established at each terminal of the equivalent circuit, corresponding to a given schedule of generation and loads at the actual stations. This can be accomplished through the medium of a set of distribution factors, determined as described in the following paragraphs. This description is given in terms of generation. The loads can be considered as negative generation and can be treated in exactly the same way.

1. In a detailed set-up of the network being reduced, with load and generator circuits disconnected, connect each interconnection bus to the analyzer neutral bus through a metering circuit. In the system of Figure 1, for example, connect points 1, 2, and 3 to the neutral bus.

2. Connect an analyzer source between one generator bus, such as terminal a in Figure 1, and the analyzer neutral bus. Adjust this source so that its output current is equal to one ampere or unit current. Measure the currents in the several metering circuits connecting the terminals to neutral.

These metering-circuit current readings are the distribution factors associated with the bus which is energized. If one of the interconnection terminals happens to be also one of the generator or load busses, it is not necessary to carry out the test for this bus. Unit-current input to this bus all would return to neutral through the metering circuit connected to the same bus. In this case, the one distribution factor is unity; the others are zero. With this exception, distribution factors are measured with unit current impressed successively at each bus.

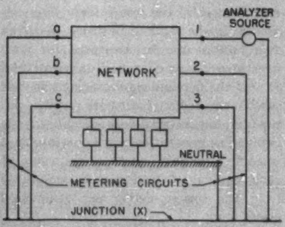

Figure 3. Network analyzer circuit connections for measuring transfer impedances

Usually, the metering circuit currents will be nearly in phase with each other and with the source current, if the ratio r/x of the major lines is reasonably uniform. If appreciable angular displacement appears, these currents or distribution factors can be measured as complex quantities, with the source current as reference, by means of the analyzer vector-metering equipment.

3. In order to establish a convenient notation for the distribution factors, let the internal busses be indicated by letters, and let the points of interconnection which are retained in measuring the equivalent line network be indicated by numbers. Use the first letters of the alphabet to indentify generator busses, and assign the remaining letters to load busses. If a load or generator appears at one of the retained busses, assign both a suitable letter and a number to this bus. When station a is energized by impressing unit current, denote the currents in metering circuits connected to terminals 1, 2, 3, . . . , by the symbols D_{a1}, D_{a2}, D_{a3}, . . . , respectively. Similarly, when unit current is impressed at station b, label the corresponding distribution factors as: D_{b1}, D_{b2}, D_{b3}, ...

4. The distribution factors are used to obtain an equivalent generation at each terminal of the equivalent line network, from known or specified power and reactive generation and bus voltages at generators in the reduced system. According to the usual practice in analyzer studies, voltages are expressed in per cent or per unit of a nominal base voltage, and power quantities are recorded either in terms of actual system value or in per unit.

Express the power and reactive loading of each station as a complex number in per unit of the chosen power base. Assuming that normal angular displacements between bus voltages are known, either from previous studies or from a special analyzer test made for this purpose, express each bus voltage in per unit as a vector quantity, with one of the retained terminals as reference. For each bus, the per unit current loading, corresponding to the scheduled power and reactive loading, is obtained by dividing the per unit vector power by the conjugate of the corresponding per unit bus voltage. If the bus angles are not known, the use, either of estimated angles or of only voltage magnitude may give sufficiently accurate results.

Represent the resulting per unit current loadings of stations a, b, c, . . . , by I_a, I_b, I_c, . . . , respectively. Denote by I_1, I_2, I_3, . . . , the equivalent generator per-unit-current loadings at terminals 1, 2, 3, . . . , respectively. The determination of these equivalent source loadings is indicated in equations 1

$$I_1 = D_{a1}I_a + D_{b1}I_b + D_{c1}I_c + \dots$$
$$I_2 = D_{a2}I_a + D_{b2}I_b + D_{c2}I_c + \dots \qquad (1)$$

and so on. The equivalent per unit source currents can be converted back into power and reactive loadings, using known or estimated tie-line terminal voltages.

5. The system generation and load can be reflected separately to the tie-line terminals in this manner, to appear as an equivalent generator and an equivalent load at each terminal, or the two can be combined into a net load or net generation at each terminal. If the currents I_a, I_b, I_c, . . . , on the right hand side of equations 1 include all busses, with the proper algebraic signs to distinguish between generation and load, these equations give the equivalent net current sources. The distribution factors, once determined, permit representation of any desired schedule of generation and load.

6. In reducing a large system containing many loads, this method may become quite lengthy and cumbersome. An approximate apportionment of the total system load at the terminals of the equivalent circuit can be carried out more rapidly as follows.

In the detailed set-up of the network being reduced, disconnect all generators, but represent all loads in the usual fashion as constant impedances to neutral, adjusted to consume the correct scheduled real and reactive power at normal bus voltage. Connect all the terminals retained in the equivalent line network through metering circuits to one terminal of a single analyzer source, which in turn is connected to neutral at the other terminal. Adjust this source to deliver unit current to the system. Read the currents in the metering circuits and label these currents d_1, d_2, . . . , as read in metering circuits to terminals 1, 2, . . . , respectively. These are treated as total-load distribution factors.

The equivalent load at terminal 1 is

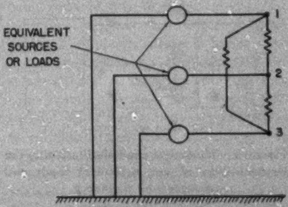

Figure 4. New simplified equivalent circuit for the system of Figure 1

taken as the product of d_1 and the total system load current. The equivalent load at terminal 2 is the product of d_2 and the total system load. The equivalent load at each of the other terminals is calculated in a similar fashion.

In the event that large loads, that is, low-impedance load circuits, appear at some of the terminals being retained, the accuracy of the equivalent loads determined in this way can be improved by modifying the procedure slightly. Disconnect large loads at any of the terminals before measuring the distribution factors. Apply the resulting factors to the total load, reduced by the total amount of load disconnected in the tests. Then, at each of the terminals where load was removed, increase the resulting partial equivalent load by the amount which was disconnected from that terminal during the measurements.

7. Another method for reducing all loads simultaneously to equivalent loads at the terminals suggests itself if the system loads are viewed as constant-impedance quantities.

Set up in detail the network to be reduced, leaving open all generator circuits, but representing loads by the proper impedance in the usual manner. Measure the transfer impedance, between the several retained interconnection points and neutral bus, as described under method *B*, and use these as the equivalent loads. If desired, the load real and reactive power can be computed, using known or estimated terminal voltages, and then these loadings can be combined at each terminal with the equivalent generator loadings.

Equivalent Generators and Loads: Method II

The method outlined here resolves directly the equivalent net generation or net load, as the case may be, at each terminal, and can be employed if the system to be reduced is set up in detail, together with the adjoining network with which it is interconnected. It may not be necessary to represent the entire adjoining network if a portion adjacent to the interconnecting ties is sufficient to establish normal power flow and voltage at the points of interconnection. Some particular power-flow condition, here termed normal flow, serves as the basis for determining the equivalent net loads and generators.

1. First, establish the normal-flow condition on the analyzer set-up and measure carefully the voltage and angle at each interconnection bus. Measure also the normal power and reactive flow over the interconnecting ties.

2. Set up the equivalent line network, with only tie-line terminals retained, and connect an analyzer source to each terminal. Adjust these sources to reproduce the normal-flow values of voltage and angle at each terminal, and record the magnitude and direction of the resulting power and reactive loading of each source. Since loads are not represented in this test, the loadings of the sources consist of real and reactive power circulated between sources by the normal-flow terminal voltage and angle differences.

3. The measured circulating flow at each terminal can be combined with the normal-flow interchange at the same terminal, to determine the equivalent net load or generator which should be placed at each terminal of the equivalent circuit. This process of combination is described best by example.

Figure 5(A) shows the normal-flow interchange and terminal voltages in a system with three ties between the two sections. Figure 5(B) gives the flow circulated between the terminals by the same normal-flow terminal voltage conditions. Figure 5(C) illustrates how the equivalent load or generator at each terminal is deduced from the information given in Figures 5(A) and 5(B). The equivalent net load or generator at a given terminal contains the real and reactive power components required to attain a balance with the normal-flow interchange and with the normal circulating flow at that terminal. For convenience in calculating the net load or generator at each terminal, the normal circulating flow is indicated by dotted sources in Figure 5(C). In reality, these flows occur in the equivalent mesh network, but it is not necessary to determine their distribution in the various branches.

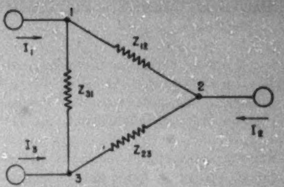

Figure 6. Typical equivalent circuit which is to be reduced further to one requiring a single source

4. When these tests are made, it is desirable to establish two or three additional conditions in the detailed portion of the set-up which represent extreme departures from normal flow, involving line outages or other emergency operating situations. The equivalent loads and generators, derived in the same way from these extreme conditions, will serve as an indication of the range of applicability of the normal-flow values, and also will serve as a guide for adjusting the equivalent reactive generation.

5. If it is desired to separate the equivalent net generation or net load at each terminal into the component parts contributed by the load and by the generation in the reduced network, distribution factors can be measured for each generator bus as described under method I. For the particular generating schedule within the reduced network, which was used in the normal-flow condition, the equivalent generation can be determined at each terminal, and then the value of each equivalent load can be separated from the corresponding net generation or net load.

Reducing the Number of Equivalent Generators

In cases where normal power interchange is from the reduced section to the rest of the system, the equivalent circuit probably will require a net generation at several of the terminals. If a sufficient number of power source units is not available on the analyzer to set up the equivalent circuit together with the adjacent detailed system, the method given here can be used to combine the generators appearing at several terminals of the equivalent circuit into a single source. The reduction to a single source introduces additional line circuits in the final equivalent network, but the shortage of analyzer sources often is more severe than that of line units.

The procedure is described in terms of an example involving a 3-terminal equivalent circuit, shown in Figure 6, with net generation appearing at each terminal. It can be extended, by analogy, to any number of terminals. In the following, all quantities are retained in literal form. A numerical example is given in Appendix II.

1. Figure 6 represents the equivalent circuit only, with connections to the adjoining detailed system not shown. The equivalent generator loadings in per unit current, complex or vector values, are indicated as I_1, I_2, I_3 at terminals 1, 2, and 3 respectively. Several intermediate steps are necessary in deriving the single-source circuit. Consider a star network, Figure 7(A), connecting three current sources equal to those shown in Figure 6. Arbitrarily assign a value of $(1.0+j0)$ to the impedance of the branch connected to terminal 1. If the other branches, Z_2' and Z_3', are chosen to satisfy the relation $I_1 \cdot 1.0 = I_2 \cdot Z_2' = I_3 \cdot Z_3'$, see equation 4, Appendix I, then the three source currents can be added together and impressed at the common junction of the star network without disturbing the terminal conditions.

2. Convert this star network to an equivalent mesh network, equation 2 of Appendix I, as indicated in Figure 7(B). Comparing the impedance values of this mesh network with those of Figure 6, multiply the impedances of Figure 7(B) by a complex constant, $\underline{/k\phi}$, which is chosen so that one branch of the resulting network is equal to the corresponding branch of Figure 6; at the same time, the other branches (those of Figure 7(B) multiplied by $k\underline{/\phi}$) are greater in magnitude than the corresponding branches of Figure 6. In this example, assume that the relation $Z_{12}' \cdot k\underline{/\phi} = Z_{12}$ satisfies this condition.

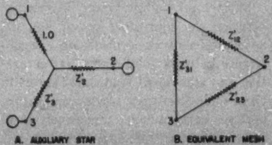
3. Next, calculate values of impedances Z_{23}'' and Z_{31}'' which, after being paralleled with $Z_{23}' \cdot k\underline{/\phi}$ and $Z_{31}' \cdot k\underline{/\phi}$ respectively, will be equal to the corresponding branches Z_{23} and Z_{31} of the original network, Figure 6. The network of Figure 8 then will have the same transfer impedances between terminals as that of Figure 6.

4. The mesh network composed of branches Z_{12}, $Z_{23}' \cdot k\underline{/\phi}$, and $Z_{31}' \cdot k\underline{/\phi}$ in Figure 8, is equivalent to the original star network of Figure 7(A), with each branch multiplied by $k\underline{/\phi}$. This star originally was established in such a way that the terminal current sources could be combined at the star point without changing terminal performance, and the constant factor $k\underline{/\phi}$ does not disturb this condition. The final equivalent circuit with a single source is shown in Figure 9.

If the source currents, representing either equivalent generation or net generation, have relatively large phase displacements with respect to each other, the procedure just outlined may produce negative resistance terms in the branches of the final equivalent circuit. It may be possible to avoid negative resistance by changing the angle ϕ. If this is done, one additional branch Z_{12}'' will appear between terminals 1 and 2.

Another way to avoid negative resistance is to divide each original source current into two parts, one a quadrature component which can be represented by a capacitor at each terminal, and chosen so that the remaining parts of all source currents are in phase. This can be stated more clearly in terms of power quantities. Assume that the terminal voltages in the present example are nearly in phase. Then, if the three generator loadings are at widely different power factors, negative resistance may appear. To avoid this, all of the real power generation is transferred from each terminal, at some convenient uniform power factor for all sources involved, to the star point; the balance of the reactive power is generated locally at each terminal by means of capacitors. If an equivalent source consumes reactive power, a shunt reactor can be used at that terminal instead of a capacitor.

This method of reducing the equivalent power sources to a single source is based on the assumption that the equivalent generator loadings are given in terms of fixed and known currents. In terms of power quantities, the single source located at the star point must generate the additional I^2R and I^2X losses incurred in the flow of current from the single source to the terminals of the equivalent circuit. This effect appears as a higher star-point voltage and as a shift in its angular position ahead of the terminal voltages. The star-point voltage and additional generation to supply losses can be estimated, in order to facilitate establishing the initial terminal conditions of the study. Then, in the course of the study, the single source is adjusted to produce the same total power and reactive input to the terminals as calculated for the original equivalent network from which the single-source circuit was derived.



A. AUXILIARY STAR B. EQUIVALENT MESH

Figure 7. Auxiliary star network and its equivalent mesh, used in the derivation of the single-source circuit

If a change of internal generating schedule in the reduced system is to be simulated, a new single-source network must be computed, unless it can be assumed that all generation which has been shifted to the star point changes loading in the same proportion.

Transformer Taps

In network analyzer studies, convenient base voltages are chosen for the various transmission and subtransmission levels, and the analyzer voltage measurements usually are taken in terms of percentages of these nominal values. Very frequently, transformers represented in a study have actual turn ratios deviating from the ratios of the arbitrary nominal values assigned to the voltage levels interconnected by the transformers. Although nominal voltage transformations do not appear in the analyzer set-up, any such deviations from nominal ratio are represented at points of transformation by adjustable autotransformers provided for the purpose. The occurrence of off-nominal turn ratios within a system should be considered in devising an equivalent circuit for the system, because these ratios may have an important effect on terminal voltages and the distribution of reactive power. Since the possible situations in regard to off-nominal transformer tap settings are so numerous, a general treatment is not attempted. Several suggestions are offered to assist in reproducing, at least approximately, the effects of transformer turn ratios.

A residual, off-nominal turn ratio, encountered in tracing from one tie line terminal to another through the system being reduced, can be represented in the equivalent circuit by connecting an analyzer autotransformer in series with one of the terminals. If n terminals are retained, and a different residual turn ratio appears between each pair of terminals, these may be represented by $(n-1)$ autotransformers at any $(n-1)$ terminals. This assumes that the product of turn ratios around any closed loops in the reduced system is unity. If this is not the case, it is possible to encounter different residual ratios in tracing through different paths between two given terminals. Normally these differences will be small, or the paths involved will be of high impedance and an average ratio can be used.

A simple test on a network analyzer can be used to determine the net turn ratio between retained terminals in a complex network. A voltage of 100 per cent is impressed at one terminal on an analyzer set-up of the complete line network, with capacitors, loads, and generators open, and with all autotransformers adjusted to represent normal transformer tap settings. The voltages measured at the other terminals can be used to compute the net turn ratios between terminals.

Transfer-impedance measurements should be made with taps set at normal value if residual turn ratios between retained terminals are small or zero. If a relatively large turn ratio exists between one terminal and the rest, it may be possible to reduce this during impedance measurements by altering the tap settings of transformers at or near the terminal in question. Then, if the turn ratio is introduced in series with that terminal of the equivalent circuit, the transfer-impedance representation will be approximately correct.

The sum of the distribution factors described under method I may not be equal to unity in the presence of off-nominal turn ratios. The distribution factors as read with normal tap settings should be applied to the source and load currents. In applying method II to determine the equivalent loads and generators, residual turn ratios between terminals should be represented during the determination of normal-voltage circulating flow through the equivalent line network.

Using the Equivalent Circuit

After the desired equivalent circuit has been derived, it is set up, connected at the proper points to the detailed representation of the adjoining system, and the desired tests are carried out on this detailed portion. Some additional suggestions are given here on using the equivalent circuit during these tests.

If the information on equivalent loads and generation has been derived in terms of per unit current, the corresponding loadings in terms of real and reactive power can be calculated, using known or estimated voltages at the tie line terminals.

If it is necessary to estimate these voltages initially, the actual conditions are established by trial on the first analyzer study. During subsequent tests, the equivalent loads are held at constant values of real and reactive power.

$k\angle\theta \cdot Z'_{31}$
$k\angle\theta \cdot Z'_{23}$
Z''_{23}

Figure 8. Mesh network equivalent to Figure 6

Assuming that generators in the reduced system are operated at a scheduled power output and fixed terminal voltage, the real power loading of the equivalent generators is held constant. The reactive loading of the actual generators, particularly those near the tie-line terminals, might vary during studies of different conditions in the adjoining system. This introduces a serious deviation from the basic assumption of constant-current sources, and gives rise to the problem of adjusting the reactive generation in the equivalent circuit. For the purpose of simplifying this problem, it is desirable to choose, as points retained in the equivalent network, busses where, in normal system operation, the voltage is held at a definite, known value. Then, only the power component of equivalent loads and generation need be determined. Equivalent reactive generation is adjusted to hold voltage. It may be helpful to calculate the equivalent generation at each terminal corresponding to the scheduled real power loading of all suppressed generators and the maximum reactive power capability of all generators and other sources of reactive power. This information can be used as a guide to avoid obtaining an unreasonable amount of reactive support from the equivalent circuit when some particularly severe emergency condition is being studied on the adjoining detailed network.

Since total tie-line power interchange between the equivalent circuit and the adjoining network depends on the difference between total equivalent generation and equivalent load, small errors in these quantities may assume major proportions in reproducing a relatively small power transfer. If inter-company ties are involved, the total transfer usually is specified. In other cases, it is well to check the initial measured transfer to or from the equivalent circuit, against the difference between generation and load plus estimated losses in the reduced system. The equivalent loads may be shaded, if necessary, to establish the correct total power interchange.

Conclusions

In steady-state power-flow studies, the treatment of system loads and generation as constant-current quantities gives a sufficiently realistic representation to warrant taking advantage of any simplification in analysis which may result. This assumption fails, however, to give a satisfactory reproduction of actual characteristics under certain conditions, notably short circuits and power swings.

A general statement on accuracy is not attempted, because the importance of various assumptions and the degree of approximation involved depend on the nature of the system being reduced. Trial on several types of power networks, and in actual system studies, has yielded good results. The equivalent circuits derived by these methods are capable, in the cases tried, of reproducing with acceptable accuracy the terminal performance of the reduced network with various emergency operating conditions represented in the adjoining system.

When an equivalent circuit is used to reproduce power flows over inter-company ties, accuracy requirements are not extremely rigid. One company, in the process of making a planning study of proposed future developments, usually has incomplete information on future plans of its neighbors, yet an approximate equivalent representation of neighboring systems may be necessary in the study. Joint studies of interconnection problems offer opportunities to obtain equivalent circuits of the systems involved as viewed from the inter-company boundaries. The methods described herein are well suited to this type of equivalent-circuit application.

Additional approximations can be employed to simplify determination of the equivalent circuit if the study at hand allows liberal accuracy limits. For example, the distribution factors in method I might be applied directly to kva loadings, neglecting voltage magnitudes and angles. A d-c board could be used to determine the distribution factors, if transformer taps are neglected and uniform impedance angles assumed.

In general, the new equivalent circuit representation occupies an intermediate position relative to methods *A* and *B* mentioned earlier in the paper. It is a more complete representation than method A, but it may lack some of the flexibility and accuracy of method B, through suppression of internal generating stations. It is intended to supplement existing methods; in practice, all three methods might be used simultaneously to advantage in some studies.

Appendix I. Analytical Methods and Basis for the Simplified Equivalent Circuit

The principles employed in methods I and II of the paper apply rigorously to an idealized network in which loads and generators maintain constant-current loadings, that is, currents fixed in magnitude and relative phase position regardless of bus voltage variations. Although these conditions are not realized in practice in a power-system network, such an idealized network is considered here for the purpose of illustrating the basis for practical applications. An analytical method is described for eliminating all busses, except the tie-line terminals in the section of the idealized network which is being reduced, and its equivalence to methods I and II is shown. This method can be adapted to the analytical determination of a power-system equivalent circuit if neither an a-c nor a d-c board is available for this purpose.

Referring to Figure 1 as an example, assume that the generators and loads satisfy the specified constant-current characteristics. Assume that connections exist to an adjoining network at the three points as indicated, and that it is desired to replace the system of Figure 1 with an equivalent circuit. Assume further that the neutral bus is common to both the section to be reduced and the adjoining section, and that the adjoining network contains at least one point of fixed or controlled voltage to neutral.

Under these conditions, the distinction between load and generation in Figure 1 is merely a matter of relative phase position of the current. Both the generators and loads can be treated alike as known, fixed, impressed currents. By Kirchhoff's law, the vector sum of the tie-line currents must be equal to the vector sum of the loads and sources (impressed currents). The equivalent circuit must reproduce the division of this total tie-line interchange among the several ties in the same manner as the actual network of Figure 1, when changes are being studied in the adjoining network. Within the section to be reduced, any bus or junction can be eliminated by a star–mesh transformation of the line impedances terminating at the junction. If an impressed current exists at the junction being eliminated, it can be removed, prior to the star–mesh transformation, by replacing it with separate currents at the neighboring junctions in such proportions that performance of the network beyond these adjacent terminals is not disturbed. New branches, appearing between neighboring junctions as a result of the star–mesh transformation, can be combined in parallel with circuits already existing between these junctions, and then the process repeated to eliminate another junction. In this way, all busses except the tie-line terminals can be eliminated, and, in the process, all source and load currents will have been shifted to these terminals to appear as equivalent impressed currents. As long as equivalence is maintained at each step, the final circuit, such as that shown in Figure 4 for the system of Figure 1, will reproduce the performance of the reduced network as viewed from the adjoining network. Hence, it is only necessary to show that this process is valid in eliminating the common junction of a general n-point star connection of impedances with a fixed current impressed at this common junction.

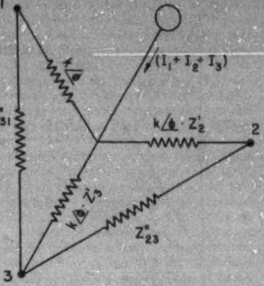

Figure 9. Final single-source circuit

The general star–mesh transformation is well-known, and is included here merely for convenience and consistent notation. Let Z_1, Z_2, $\ldots$, Z_n represent the impedances connected from the common junction to terminals 1, 2, $\ldots$, n, respectively, of an n-point star network. In general terms, let j and k denote any two of the n terminals. Then Z_{jk} represents the impedance between terminals j and k in the equivalent mesh network and its value is given by

$$Z_{jk}=Z_jZ_k\left(\frac{1}{Z_1}+\frac{1}{Z_2}+\frac{1}{Z_3}+\ldots+\frac{1}{Z_n}\right) \qquad (2)$$

An impressed current (representing either a source or a load) existing at the common junction of an n-point star can be divided into n parts and relocated at the n remote terminals of the star. If the total impressed current remains the same and the voltage differences between the terminals of the star are not disturbed, the performance of the network beyond the terminals of the star will be the same. In general terms, let I_k represent the portion of the original impressed current, I, which is shifted to terminal k. The following relations must be satisfied to preserve equivalence of the modified network

$$I=I_1+I_2+I_3+\ldots+I_n \qquad (3)$$

$$I_1Z_1=I_2Z_2=I_3Z_3=\ldots=I_nZ_n \qquad (4)$$

By combining the relations given in equations 3 and 4, the values of the new impressed currents at the terminals can be determined. In general terms, this leads to the following expression for the portion of the original impressed current to be transferred to terminal k

$$I_k=I/Z_k\left(\frac{1}{Z_1}+\frac{1}{Z_2}+\ldots+\frac{1}{Z_n}\right) \qquad (5)$$

This method of eliminating junctions containing impressed current accomplishes the same result as a reduction formula in matrix or tensor form discussed by Kron.[1] In the case where n is equal to two, equation 5 reduces to the familiar relation for replacing a tap load on a line section by equivalent loads at the two ends of the line.

In carrying out successive applications of this reduction, it is desirable to identify the original impressed currents by letters or symbols, and to retain them as literal rather than numerical expressions, keeping a record of the numerical coefficients of these currents as junctions are eliminated. When the process is completed, that is, when all except the tie-line terminals have been eliminated, all of the original sources and loads will have been shifted to the retained terminals with, in general, a portion of each appearing at each terminal. Upon collecting coefficients of like terms in the expression for the total equivalent impressed current accumulated at each tie-line terminal, the distribution factors of equations 1 will be obtained. Any desired schedule of source and load currents in the original network can be converted into equivalent currents impressed at the tie-line terminals by equations 1.

Either method I or method II of the paper can be applied to the idealized constant-current network to obtain the same result as that yielded by the analytical method just described. In the case of method II, the normal-flow interchange and the normal circulating flow would be expressed in terms of current rather than power quantities.

The equivalence of these different methods can be demonstrated by the principle of superposition. Any voltage differences existing between the tie-line terminals can be considered as arising from currents circulating through the line network of the reduced system, with the source of these circulating currents residing in the adjoining system. If the tie-line terminal voltages are equal, there can be no circulating currents; in the equivalent circuit, the impressed current at each terminal then will be equal to the tie-line flow at that terminal. In other words, the equivalent impressed currents are equal to the corresponding tie-line currents in the actual network, when the circulating currents are suppressed. In method I, the circulating currents are suppressed by connecting all tie-line terminals together. The resulting natural distribution of each internal impressed current in the tie lines is measured separately, and then equations 1 accomplish the proper superposition of the effects of all internal impressed currents.

In method II, any arbitrary "normal" operating condition of the complete network is used as a basis. The circulating-current components of the resulting tie-line flows are determined by impressing the "normal" voltage differences at the terminals of the equivalent line network, and then the equivalent impressed currents are obtained by separating the circulating components from the "normal" tie-line loadings.

Appendix II. Sample Calculation of Single-Source Equivalent Circuit

It is assumed that the equivalent circuit of Figure 6 has been derived to replace a power-system network, and that an additional reduction in the number of sources is necessary before this circuit can be used in the detailed study of an extensive system, to which it is interconnected at terminals 1, 2, and 3. The numerical values associated with the equivalent circuit are:

Impedances in per cent on 100,000 kva base

$Z_{12}=11+j40=41.4\underline{/74.6}$ degrees
$Z_{23}=6+j24=24.8\underline{/76}$ degrees
$Z_{31}=34.8+j118=123\underline{/73.6}$ degrees

Source currents in per unit (referred to voltage at terminal 1)

$I_1=0.57-j0.19=0.60\underline{/-18.5}$ degrees
$I_2=1.61-j0.70=1.76\underline{/-23.5}$ degrees
$I_3=0.10-j0.12=0.156\underline{/-50.2}$ degrees

It is assumed further that the impedance angles are sufficiently uniform to use scalar impedance with a constant impedance angle of 74 degrees, and that normally the interconnection terminal voltages are displaced only a few degrees. These latter assumptions are not required by the method, but they simplify calculations in cases where they can be made.

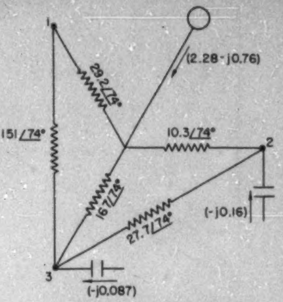

Figure 10. Single-source equivalent circuit derived in the numerical example

Values of current are in per unit; impedances are in per cent on a 100 megavolt-ampere base

In order to avoid negative resistance and to permit scalar computations, the original source currents are modified by separating each of the currents I_2 and I_3 into two parts: a quadrature component to be generated by a capacitor, and the remaining portion to be combined at a new junction established later. The portion of each which is to be moved to the new junction is chosen so that the phase angles of all three currents are the same. These modified source currents, used in subsequent calculations, are

$I_1=0.57-j0.19=0.6\underline{/-18.5}$ degrees
$I_2=1.61-j0.54=1.7\underline{/-18.5}$ degrees
$I_3=0.10-j0.033=0.105\underline{/-18.5}$ degrees

In the auxiliary star network of Figure 7(A) the values of Z_2' and Z_3' are $0.353\underline{/0}$ degrees and $5.71\underline{/0}$ degrees respectively, from the relation $0.6\cdot1.0\underline{/0}$ degrees $=1.7\cdot Z_2'=0.105\cdot Z_3'$; the branches of the equivalent delta, Figure 7(B) are: $Z_{12}'=1.42$, $Z_{23}'=8.06$, and $Z_{31}'=22.86$. By inspection, the ratio Z_{12}/Z_{12}' is larger in magnitude than the corresponding ratios of the other branches, hence the value of k/ϕ is taken as $(41.4\underline{/74}$ degrees$)/(1.42\underline{/0}$ degrees$)=29.2\underline{/74}$ degrees.

When the impedances in Figure 7(B) are multiplied by k/ϕ, the branch between terminals 1 and 2 in the resulting network is the same as the corresponding branch in the original equivalent circuit of Figure 6. Additional branches of the proper impedance can be connected between other pairs of terminals, see Figure 8, to make the resulting network entirely equivalent to that of Figure 6. This requires, in the present example: $(Z_{23}''\cdot k\underline{/\phi}\cdot Z_{23}')/(Z_{23}''+k\underline{/\phi}\cdot Z_{23}')=Z_{23}$; or $Z_{23}''=27.7\underline{/74}$ degrees, and, similarly, $Z_{31}''=151\underline{/74}$ degrees.

Since the network of Figure 7(B), with all branches multiplied by $k\underline{/\phi}$, is contained in Figure 8, this portion may be replaced by the star from which it was derived, Figure 7(A), with all impedances multiplied by k/ϕ. The sum of the modified source currents can be impressed at the common junction of this star, and the residual quadrature components of source currents can be impressed at the terminals to obtain the final equivalent circuit, requiring a single power source, as shown in Figure 10.

Discussion

R. D. Goodrich, Jr. (United States Bureau of Reclamation, Denver, Colo.): Ward's introduction of the constant-current-type equivalent circuit is a distinct contribution to the technique of a-c network-analyzer operation. It provides a quick and simple method for representing the essential feature of a secondary network, namely, its ability to transfer power from one point of interconnection with the main network to another.

If power flow at the points of interconnection with the main network is the only purpose for which the equivalent circuit is required, it would appear that the equivalent generators in Figure 5(C) could be adjusted by trial rather easily, and thus the labor of computing the fictitious power outputs of these units could be avoided. If the equivalent generator at one point of interconnection is omitted, there should be only one combination of adjustments of the remaining generators which will yield the desired values of interchange power. The significance of individual generator powers in the equivalent circuit will, however, be lost.

Where a more complete equivalent circuit is required, as in stability studies, for example, it has been found convenient to use the star-type equivalent circuit, shown in Figure 1 of the discussion, corresponding to the mesh equivalent of Figure 2 of Ward's paper.

It can be proved mathematically that the two equivalent circuits are interchangeable. However, the star equivalent has the advantages that:

a. It requires less impedance units to set up.

b. It permits the elimination of an impedance leg, if no connection is to be made to it.

c. It allows, in some cases, the alteration of an impedance to simulate a change in line reactance, generator reactance, or total system load.

The star equivalent has the disadvantage that the evaluation of Z_a, Z_b, and so on requires the solution of a set of simultaneous equations, one equation for each unknown impedance. However, the symmetry of the coefficients of the unknowns simplifies the labor involved.

To determine the Z's, a reasonable power flow first is established in the secondary network on the network analyzer. Then the secondary network is disconnected from the main network and from the generator units, and a meterable jumper is connected to each point to be retained, including the ground bus. In some cases, it is permissible to bus together all of the points of generation in the secondary network, so as to retain a single equivalent generator. The final step of analyzer operation is to measure the impedance between each pair of jumpers, with the other jumpers separated electrically.

The series of readings obtained gives values of Z_a+Z_b, $Z_a+Z_c \ldots Z_2+Z_3$. Evidently, for the 7-point network shown in Figure 1 of the discussion, 21 such equations can be written, but, since there are only 7 unknowns, 14 of the equations are redundant. Although it has certain limitations, the method of least squares often is considered to yield the most reasonable values for the unknowns under these conditions. The least squares procedure is as follows: first, multiply each of the original observation equations by its coefficient of the first unknown, Z_a, and add the products. Since the coefficient of Z_a is one in six of the equations, and zero in the rest, six equations will be added together to yield a normal equation of the form

$$6Z_a+Z_b+Z_c+Z_G+Z_1+Z_2+Z_3=M_1$$

Next, multiply each observation equation by its coefficient of Z_b, and add the products. The second normal equation will, therefore, be

$$Z_a+6Z_b+Z_c+Z_G+Z_1+Z_2+Z_3=M_2$$

This process is repeated until seven normal equations have been formed; their solution will yield the impedances desired. The resulting equivalent circuit will be

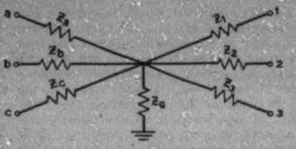

Figure 1. Star type of equivalent circuit

found to simulate very closely the effects of the original system, both for steady state and for transient conditions.

C. E. Parks (Public Service Company of Indiana, Inc., Indianapolis, Ind.): The author is to be congratulated for his novel approach to the subject of the setting up of equivalent circuits for power-flow studies on an a-c network analyzer.

Most electric utility companies are now employing the a-c network analyzer in the solution of present, and future, system operation and development problems. A large majority of the systems now being analyzed on the calculating board are interconnected with at least one other company. Where these interconnections become numerous, the problem of representing the adjacent system's transmission line set-up, taking into account that system's possible development in the future becomes a very important factor in the study under consideration. If the adjacent system is set up in detail, it usually requires that a joint study be conducted. While such joint studies are very desirable, they consume the time and effort of the operating engineers of both companies involved. Such an arrangement will result usually in abbreviating the system set-up for both systems involved, because of the limitations for board facilities, and further generally will limit the number of studies that can be conducted in a prescribed period.

The author of this paper, since he is engaged actively in power-flow studies of the numerous systems which employ the Purdue network analyzer, has appreciated this problem, and in his excellent paper, has presented a very sound solution of the problem.

The methods that he suggests have been employed in power-flow studies made by the Public Service Company of Indiana, Inc. It has been found, by actual practice, that the results obtained by using the equivalent circuits established by these methods has proved sufficiently accurate in the solution of the study being conducted. Other methods of representing the adjoining systems network have been tried out by our company, but it has been found that the method presented by the author in this paper produces by far the most accurate results.

Again, may I congratulate the author in his fundamental thinking in the development of the ideas presented in this paper, and express the hope that other operating companies will make use of this time- and labor-saving tool in their future studies.

Glenn W. Bills (Bonneville Power Administration, Portland, Oreg.): There is a definite need, by those engineers who use a-c network analyzers, for the type of equivalents introduced by this paper. It is a welcome contribution and should prove useful to most utilities that have calculating boards. Although the Bonneville Power Administration's a-c analyzer has 18 board generators, the Northwest Power Pool contains more interconnected systems than can be set up in detail; thus, we require equivalents.

In many problems on our board, these equivalents contain too many impedance units, since there are generators in the networks we desire to reduce. Ward's method supplies an ingenious method for reducing the number of impedances needed and allows for changes in loads and generation. In the majority of our studies, generators and loads are maintained at constant power output, and usually the reactive power changes very little so that it isn't necessary to be able to alter these. However, to be able to reduce the number of generator sources is of much value, and the author should be complimented on his neat scheme for reducing the number of equivalent generators.

We have attacked the problem of equivalents and solved it in another way. It is based on the fact that generators can be replaced by negative impedances in analytical solutions, assuming constant impedances. To do this on an a-c analyzer, we have developed an electronic negative impedance capable of use with the analyzer. This means that a system to be reduced can have its generators replaced by the negative impedances, and transfer impedances may be measured between the network terminals, as in method B described in the paper. Should any of these impedances contain negative resistances, one of our negative impedances can be used to represent it. In this fashion, it is possible to eliminate the use of distribution currents, which, as Ward has pointed out, can be quite "lengthy and cumbersome." Incidentally, these negative resistors can be used as board generators in conjunction with the ordinary board generators, as well as provide a representation of negative resistor elements. However, even with negative resistors, it is helpful to have a method for obtaining single-source equivalent circuits in parts of systems remote from the central portion being investigated. In this connection, negative impedances would simplify the procedure given by Ward to secure a single-source equivalent. In those cases where negative resistances appear, they easily can be represented by the electronic units, thus obviating the need for mathematical stratagems, such as "changing the angle ϕ," to eliminate negative resistances.

The author's pertinent comments on the effect of transformer taps in obtaining equivalents should be helpful to those who have had to contend with interconnected systems. Few, if any, articles have mentioned this subject, and the author deserves praise for bringing it to the attention of system engineers.

Now that at least two methods exist for obtaining satisfactory steady-state power-flow equivalents, it is desirable to obtain one which would be satisfactory for power-swing studies. In those cases where the generators are in an area electrically remote from the network upon which are inflicted shocks, such as line faults and line clearances, the generators usually oscillate together as a unit.

For such cases, equivalents are measured by means of method B, the generators in the network being represented by their transient impedances. The end result is an equivalent which contains a single equivalent generator. However, the equivalent rarely satisfies the initial steady-state conditions at the retained terminals and is not rigorous. It should be possible, by means of an extension of Thévenin's theorem to n terminals, or by some other device, to determine an equivalent which would be much more satisfactory than those used at present in swing studies. If any system engineers or network specialists know of such a method, it would be appreciated greatly if they would publish a paper on the subject.

R. J. Tallent (Ebasco Services, Inc., New York, N. Y.): Ward has developed equivalent-circuit methods which are quite an improvement over the old conventional methods. Power systems have grown so large, and interconnections have become so common, that it has become quite difficult to condense, by the conventional equivalent methods, some systems sufficiently to get them on the board. It has been a problem to set up the critical sections in enough detail so that line loadings and voltages may be observed, and yet leave enough board generators and impedance elements to accurately reproduce the adjoining system. By using Mr. Ward's method, it is possible to reduce considerably the number of elements in the adjoining-system equivalent.

The method in the paper described under method I, paragraphs 1 through 5, would give a flexible set of results suitable for readily representing a variety of load and generation conditions, but, as noted, the work involved in reducing a large system with many loads would become lengthy and time consuming.

The methods described under method II, paragraphs 1 through 5, are an improvement on the above insofar as reducing labor and time, but have the disadvantage of requiring both systems to be set up simultaneously. This requirement nullifies one big advantage of the method, since shortage of analyzer elements is frequently the motivating reason for using equivalents. Also, as recognized, results are not as flexible, since they pertain only to a given generation and load condition.

The method described in paragraph 6 under method I sounds promising and practical. However, as described, the results would not include the effect of varying generation in the neighboring system. This would limit its usefulness to a degree. If this method could be extended simply to include generation effects, it would find frequent application, since it would be very easy to carry out, requiring only one system set up at a time. Results would be accurate enough for a large variety of studies, presuming, of course, the studies deal with like load conditions and the same system.

Perhaps, by applying the superposition principle, it may be possible to extend this method to include generation effects without either increasing the work and time appreciably or causing need for major set-up reconnection, such as disconnecting loads.

This might be done in the manner described below.

1. Proceed as described in paragraph 6 and obtain load distribution factors for the interconnection points.

2. Next alternately and singularly connect, by a metering lead in parallel with the leads to the interconnection points, the various generating buses to the board generator. Adjust loads and record flows in each metering lead for each generating bus.

3. By application of the superposition principle, the distribution factor for each generating plant to the interconnection points may be obtained by subtracting results of step 1 from step 2, and dividing by the flow in the lead to generating bus.

4. The net load at each interconnection point may be computed by following equation:

$$Load_1 = D_1(Load) - D_{1a}(MW_a) - D_{1b}(MW_b) \ldots .$$

where

D_1 = distribution factor for loads as obtained in step 1 for interconnection point 1

Load = total system substation load

D_{1a}, D_{1b} = distribution factor for power plants *a* and *b* to the interconnection point 1

$Load_1$ = net load or generation at interconnection point 1

5. Adding these equivalent loads or generations to the interconnection points, and connecting these points by the transfer impedance between them, will give a close equivalent.

Edward W. Kimbark (Northwestern University, Evanston, Ill.): The representation of a multiterminal active network by a mesh of impedances, with a constant-current source at each terminal, as described by Ward, is really an extension of Norton's theorem to a network of more than two terminals.

Thévenin's theorem, in which a 2-terminal active network is replaced by an equivalent circuit consisting of a constant-voltage source and an impedance in series, is known and used now by many power engineers.

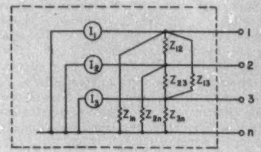
Norton's theorem, the dual of Thévenin's theorem, is not so well known. According to Norton's theorem, a 2-terminal active network can be replaced by the parallel combination of an impedance and a constant-current source. The impedance is the same as that of Thévenin's theorem. The current is equal to the short-circuit current of the original network.

Another fact not generally known is that Thévenin's and Norton's theorems can be extended to networks having more than two terminals. Instead of one impedance branch, there is now a branch between each pair of terminals. These impedances can be found by reduction of the original network after short-circuiting each constant-voltage source and open-circuiting each constant-current source in that network. Thévenin's equivalent circuit has a constant-voltage source in series with each terminal, except the reference terminal, equal to the open-circuit voltage between the corresponding terminal and the reference terminal. Norton's equivalent circuit has a constant-current source shunted between the reference terminal and each other terminal. The current of each source is equal to the short-circuit current of the corresponding terminal.

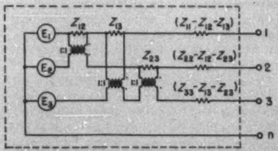
J. B. Ward: Tallent points out a disadvantage of method II in the necessity of setting up simultaneously the network to be reduced together with the section to be studied in detail. On the surface, if such a set-up were possible, it might seem that the equivalent circuit was not required. The author had in mind a particular situation in proposing method II, namely, the occasional necessity of interconnected operating companies making joint studies wherein skeleton representations of the major transmission networks are used to permit setting up simultaneously the several systems and studying interconnection problems of mutual interest. While such a set-up is available on the analyzer, it is a simple matter to obtain equivalent circuits by method II. Then these equivalent circuits will be useful in subsequent detailed studies made by the separate companies on their individual systems.

In connection with Tallent's comments on the approximate apportionment of load in paragraph 6 under method I, it was intended that the equivalent generation be obtained by separately measured distribution factors, with loads disconnected, as described in preceding paragraphs 1 to 5. Tallent's discussion outlines an interesting application of superposition, leading to essentially the same result with loads left connected.

The star-type equivalent circuit suggested by Goodrich is not interchangeable with the mesh circuit, Figure 2 of the paper, in the sense of exact general equivalence. For a general *n*-terminal circuit, a minimum of $n(n-1)/2$ links is required in an equivalent circuit.[1] The links of the circuit in Figure 2 of the paper, expressed as admittances, are the *D* coefficients of Starr's paper. The *C* coefficients of Starr's paper, which are commonly known as "self" and "mutual" constants,[2] may be arranged in an exact equivalent circuit, in the form of a star network with mutual coupling between branches. For the sample system of Figure 1 of the paper, this would appear as a star connection of six legs, with the common junction at the seventh terminal and with mutual coupling between each pair of the six legs, thus providing the required minimum of 21 impedances. Goodrich presents an interesting method for seeking the "best fit" of impedances in an approximate star network without mutual coupling. It is noted that the general "normal" equations for a given number of points of entry need be solved only once, since the coefficients are fixed by the number of terminals. Then this solution may be applied to any problem involving the same number of terminals. A simple relationship between self and mutual constants and the "through" impedances used by Goodrich is developed in Starr's paper.



A. NORTON'S EQUIVALENT



B. THÉVENIN'S EQUIVALENT

Figure 2. Generalized equivalent circuits

The reduction of a network containing sources as described by Bills treats both generation and loads as constant impedances, while, in the present paper, these quantities are considered primarily as impressed currents. The successful use of the two different approximations of power-system load and generator characteristics seems to indicate that, for the normal power-flow type of study, there is considerable freedom in designing equivalent circuits, based on combinations of the two viewpoints. If it is not necessary to deal with changes in loads, their representation as constant impedances lends itself more readily to wholesale reduction to equivalent loads at the tie-line terminals.

Kimbark's discussion brings out the close relationship between Norton's theorem and Thévenin's theorem. Although most power-system networks do not conform exactly with the idealized network characteristics on which these theorems are based, it is felt that there could be more widespread and effective application of these principles in power network analysis. Figure 2 of the discussion is submitted to supplement Kimbark's pertinent comments on extension of these theorems to more than two terminals. Two equivalent circuits are shown for a 4-terminal active network. Terminal *n* is taken as the reference terminal, corresponding to neutral in power networks. Note that the star-with-mutual circuit mentioned previously is shown in the generalized Thévenin equivalent circuit. This form yields a close analogy with the familiar 2-terminal case.

In the generalized Norton's equivalent, the links are transfer impedances, and the current sources are equal to the short-circuit currents obtained by connecting terminals 1, 2, and 3 simultaneously to *n*. The methods of the paper lead to a circuit of this type, and the impedances to neutral will appear if loads are retained as constant impedances. The voltage sources in the generalized Thévenin equivalent are the open-circuit voltages of the original network, measured with reference to terminal *n*. It should be emphasized that the self and mutual impedances appearing in Figure 2(B) of the discussion are not the same as the transfer impedances in Figure 2(A) of the discussion.

Vibrating Reed Selectors for Mobile Radio Systems

A. C. KELLER

L. G. BOSTWICK
NONMEMBER AIEE

A NEW TYPE of signaling system has been developed for mobile radiotelephone service in the Bell Telephone System. This new system is described in a paper by H. M. Pruden and D. F. Hoth.[1] The basic selection of this system is performed by the use of vibrating reed selectors which are described in this paper.

Description of Selectors

A schematic diagram of the vibrating reed selector is shown in Figure 1. The vibrating reeds are attached to a block to form a small tuning fork, the tines of which are made of a suitably stable magnetic material, and are about an inch or less in length. A pole piece attached to a small magnet is positioned centrally between the ends of the tuning fork tines. Vibration of the tines takes place when the surrounding coil, shown in Figure 1, is energized with the proper voltage and frequency. The alternating magnetic field produced by the current through the actuating coil, increases and decreases the magnetic flux in the gap between the pole piece and the tines. This flux change in turn produces similar changes in the motion of the reeds. A light contact may be closed during a fraction of each cycle of vibration.

Two types of selectors are used in the mobile radio signaling system: the first, Figure 2, is a magnetically-operated tuning fork with an associated contact; the second, Figure 3, is similar except that the contact is omitted. The contactless type is used in a circuit to give filter characteristics as described later in this paper.

Vibrating reed selectors may be used singly or in groups, and in the latter case may be operated by a common actuating coil. The two types used in the new mobile radio signaling system are shown in Figures 4 and 5. Figure 4 shows the type used in the mobile station in which four selectors, each equipped with a contact, are operated by a common coil surrounding the four selectors. Figure 5 shows the type used in the fixed-station equipment, in which each selector is associated with an actuating coil. Each of the group of selectors shown in Figure 4 is provided with a plug-type base, so that they can be changed as needed. The four selectors, each of a different frequency, determine the mobile-station number or code. By changing the frequency of one or more of the selectors, the number of that particular mobile station is changed.

Use of Selectors in Signaling System

In designing a multifrequency signaling system using these selectors, a choice must be made as to the number of available frequencies, the number of selectors at each mobile station, and as to whether simultaneous or sequential operation be used.

It was decided to use simultaneous operation, that is, all frequencies to be transmitted at the same time. This was done to improve the margin of satisfactory operation in the presence of various types of noise, fading, and so forth, as compared with pulse or sequence operation of equal operating speed.

The number of frequencies required, and the number of frequencies needed at each mobile station, is determined by the number of different combinations it is possible to make. If n frequencies are available, it is possible to make ${}_nC_r$ different combinations of r frequencies where

$$ {}_nC_r = \frac{n(n-1)(n-2)\ldots(n-r+1)}{r!} $$

For common-carrier mobile-telephone service, it appeared necessary to be able to select any one of 10,000 stations. Such a large number of selections can be achieved by using different values of n and r as indicated below:

r	n	${}_nC_r$
3	41	10,660
4	24	10,626
5	19	11,628
8	16	12,870

As can be seen, 24 frequencies taken four at a time will provide more than 10,000 choices. However, to realize the full number of selections with this combination, requires a random code and more apparatus for translation, than with other values of n and r. For example, simpler translation of a 4-digit directory number designating a mobile station results from using two groups, each of 15 frequencies, with a combination of two frequencies, in one group associated with the thousands and hundreds digits, and a combination of two frequencies in the other group associated with the tens and units digits. There are, of course, many other possible combinations, but for reasons discussed in the contemporary paper already referred to, two groups of 16 frequencies, ranging from 350 to 850 cycles, are used in the mobile-radio system.

Performance Characteristics of Mobile Station Selectors

The suitability of these vibrating reed selectors for mobile-radio selective signaling depends primarily upon their sensitivity at their nominal frequencies, upon their selectivity or discrimination against other frequencies, upon their operate times, and upon their stability with temperature and time. The first three of

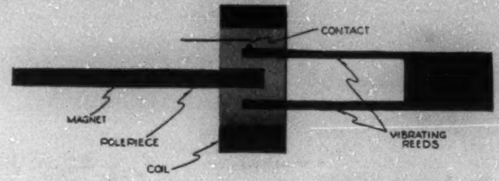

Figure 1 (left). Schematic diagram of vibrating reed selector

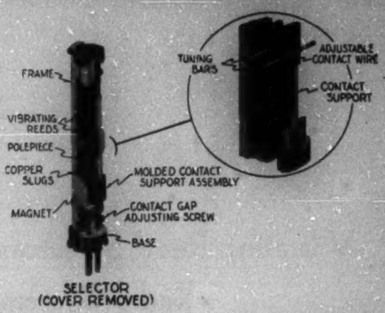

Figure 2 (right). Vibrating reed selector with contact

these factors in turn depend to a large degree upon the sharpness of tuning, or the Q of the mechanical vibrating system. In general, if the Q of a given fork is made larger, the current through the drive coil at the resonance frequency, necessary to vibrate the fork at the contact amplitude, becomes smaller in relation to the corresponding current at other frequencies. In other words, the higher the Q, the greater the sensitivity and selectivity. On the other hand, the operate time, or the time required for the tine amplitude to reach the contact amplitude, is also proportional to Q. If Q becomes too large, this build-up time becomes prohibitive. Furthermore, if Q is too large, the frequency bandwidth over which the sensitivity is within a 3-decibel range becomes so small that frequency drift in the electric supply source, and in the reeds themselves because of temperature changes and other causes, becomes troublesome in over-all system operation.

With these considerations in mind, and after some development experience in controlling frequency variations with temperature, a Q range was chosen to give a constant bandwidth (equal to resonance frequency/Q) of 1.2 cycles throughout the frequency range for selectors. This required that the Q vary directly with frequency, from about 300 at the lowest frequency to about 670 at the highest. With this choice of bandwidth, the operate time is always under 0.5 second for the lowest input level from the radio receiver, under the worst marginal conditions. The operate time is the time t required, after closing the circuit, for the fork tines to reach a contact amplitude a_t, and is related to the Q, the resonance frequency f, and the final steady state amplitude A as follows

$$a_t = A\left(1-\epsilon^{-\frac{\pi f t}{Q}}\right)$$

To obtain this adjustment of Q, electromagnetic damping was adopted, after considering other means, because of its relative independence of temperature. This damping is applied by means of copper collars slid over the pole piece to give short-circuited turns in the magnetic field, as shown in Figure 2.

The effect of the damping upon the sensitivity and the selectivity characteristics of the selector is shown by Figure 6. Plotted here on a relative decibel scale is the source power necessary to operate a selector with and without damping, and having Q values of 280 and 735, respectively.

The sensitivity of the selectors at their resonance frequencies depends upon several factors in addition to Q; these include the electromechanical coupling or force factor, the effective vibratory mass, the contact spacing, and the frequency. As used for mobile radio with four selectors in a common drive coil, about 0.7 milliwatt available source power is required at each frequency to operate the contacts.

The tuning of a selector is accomplished by bending the tuning bars as shown in Figure 2. By bending these toward the base of the selector, the frequency is increased; by bending away from the base, the frequency is lowered. This effect is the result of changing the effective mass of the reeds. With these tuning bars, it is possible to adjust the frequency of the selectors within 0.05 cycle of the desired frequency.

Avoiding excessive variations in the

resonance frequency of the selectors with temperature has been one of the most difficult problems in the development. As used for mobile radio, selectors may be called upon to operate over a temperature range of −40 to +185 degrees Fahrenheit. Throughout this wide temperature range, the resonance frequency of the selector must not drift more than ±0.5 cycle from its nominal adjusted frequency at some median temperature, to meet over-all system requirements. Frequency changes with temperature occur primarily because of: changes in the elastic modulus of the time material; changes in dimensions, as effected by expansion; and changes in the flux density in the gap between the tines and the pole piece. This gap flux density affects the frequency because of the negative stiffness of the magnetic field, a well-known effect in electromagnetic driving systems. To keep changes in frequency within tolerable limits, materials have been used with low temperature coefficients of modulus and expansion, and with the most uniform magnetic characteristics. Furthermore, one effect has been used to compensate another, with the result that an integrated design has been achieved with temperature–frequency characteristics like those shown in Figure 7.

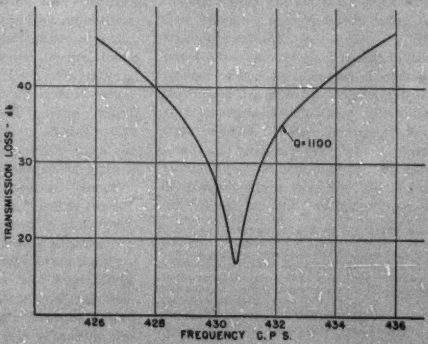

Figure 10 (right). Typical transmission loss characteristic of a reed filter sharply selective filters in the frequency source at the fixed station of the mobile-radio system. Such sharply selective circuits are obtained by making the driving coil of the selector one arm of an impedance bridge that is unbalanced near the resonance frequency by the electrical motional impedance of the selector. Such a selective circuit is shown in its simplest form in Figure 8. In addition to the driving coil, the bridge consists of two resistances and a balancing coil. The balancing coil simulates the damped impedance of the coil with the fork, and balances the bridge at frequencies that do not cause appreciable vibration of the fork. Under this balanced condition, the transmission loss through the bridge is large. On the other hand, at frequencies near the resonance frequency of the selector, the electrical motional impedance caused by vibration of the fork will unbalance the bridge, and the transmission loss will be reduced sharply, by an amount depending upon the degree of unbalance. The electrical motional impedance is inversely proportional to the mechanical impedance of the reed and has the same phase constant Q. Consequently, the transmission loss and phase shift through the bridge will vary rapidly with frequency near the resonance of the reed. For this mobile-radio application, a multiplicity of selectors, each with a driving coil and a balancing coil, are bridged on a common source of complex wave form. Each selector circuit, with its balancing coil, forms a bridge with two other common impedance elements, and selects from the complex wave form those frequencies near the resonance frequency of the fork.

For this filter application, the selectors are given a Q in excess of 1,000 by omitting the damping slugs previously described for the mobile selectors, and by using a cover shell of high resistivity to reduce eddy currents. A typical impedance characteristic of such a selector is shown in Figure 9. Figure 10 shows a typical transmission loss curve of a selective circuit like that in Figure 8. At frequencies 15 cycles or more away from resonance of the selector, the transmission loss is greater than 50 decibels.

Vibrating Reed Selective Signaling System for Mobile Telephone Use

HAROLD M. PRUDEN
NONMEMBER AIEE

DANIEL F. HOTH
NONMEMBER AIEE

MOBILE telephone service is furnished by the Bell Telephone System through land radio stations connected to the wire telephone system. Since the number of radio channels available for this service is limited, it is necessary for a fairly large number of mobile stations to share the use of a single channel. In order that a mobile station may receive telephone calls, some means must be provided whereby the mobile-service operator may call the desired car. In many radio systems, this is accomplished by providing in each car a loud speaker which is in operation at all times, the desired car being called by voice. Such an arrangement has the disadvantage that the occupants of all the telephone-equipped cars hear all conversations on their channel. This is annoying and results in a reduction of privacy. Therefore, all Bell System common-carrier mobile-telephone systems use selective signaling arrangements, which enable the mobile-service operator to ring a bell in the desired car by dialing the car's telephone number.

The selective signaling system now in use involves the alternate transmission of a succession of 600- and 1,500-cycles per second pulses, under the control of the operator's dial. Each time the tone frequency is changed, a code wheel in the mobile station is stepped around one position. Five trains of pulses are transmitted, the total number of pulses being 23 or, in some cases, 25. If the proper number of pulses in each train is received, the code wheel steps to its 23rd position and the bell rings. If the wrong number of pulses in any train is received, the code wheel drops back to its starting position and therefore never reaches the 23rd position. This type of selective-signaling system, while reliable, has some disadvantages in that the mobile equipment is fairly expensive, physically large, requires a considerable amount of audio-frequency power from the radio receiver, and provides fewer number combinations than is desirable.

The vibrating reed selector, described by Keller and Bostwick,[1] provided an opportunity for the development of an entirely new type of selective-signaling system, a trial of which is now in progress. The new system has the principal advantages of a greater number of possible code combinations (10,000), and mobile signal-receiving equipment of lower cost and smaller physical size, requiring less audio-frequency power for operation.

Description of the System

Figure 1 shows a generalized block diagram of a mobile telephone system equipped for selective signaling. The land station is equipped with a signal-sending circuit, which, under control of the operator's dial, will deliver to the land radio transmitter a series or combination of audio-frequency tones peculiar to the mobile station being called. Each car is equipped with a signal-receiving circuit which is connected to the audio-frequency output of the radio receiver at all times except when a call is in progress. When the proper series or combination of tones is received, the signal-receiving circuit is actuated, ringing the call bell in the car. Except when maintenance or repair work is required, the land station is completely operated from the traffic switchboard by a telephone operator who may handle other types of telephone traffic as well. Therefore, the system is arranged so that its operation is, as nearly as possible, like that of other telephone facilities. Standard switchboard equipment and circuit arrangements are used.

The new signaling system, as well as the one now in use, fits into the type of radio system just described. However, the new system is basically different in the mode of operation. It was decided, early in the development program, to reject all systems requiring the transmission of a sequence of pulses to the mobile station, in favor of a type of signaling that could be applied continuously. A continuously applied signal is able to overcome difficulties caused by interference or fading, since it is necessary only to apply the signal for a sufficiently long interval to ring a bell. In contrast, signaling systems which depend on the transmission of a sequence of pulses are subject to failure or possible false operation whenever a pulse is mutilated or lost because of poor transmission conditions. The continuous-signal arrangement has the additional advantage that it makes possible an extremely simple signal-receiving circuit in the mobile station.

In the vibrating reed signaling system, the land station is equipped with a source of tones of 32 different audio frequencies. When the operator dials, a relay device, known as a sender, selects four of these tones, which are transmitted simultaneously over the land radio transmitter for a period of about four seconds.

Each mobile station is equipped with four vibrating reed selectors tuned to four different tone frequencies. A different combination is used at each mobile station. These selectors are miniature electrically-driven tuning forks equipped with contacts which close when the forks vibrate. When the proper four tones are received, the four selectors vibrate, their contacts close, and a circuit is operated which rings the bell in the car. Since no other mobile station is

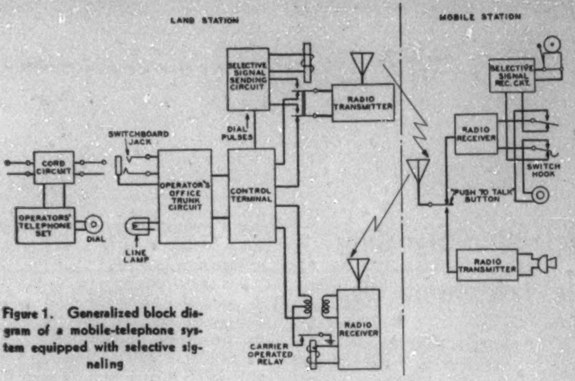

Figure 1. Generalized block diagram of a mobile-telephone system equipped with selective signaling

equipped to respond to the same combination of frequencies, no other bell rings.

The tone frequencies used are spaced 15 cycles per second apart. They are divided into two groups, the lower of which includes frequencies from 352.5 to 577.5 cycles per second, and the other includes frequencies from 607.5 to 832.5 cycles per second. This frequency range was chosen because it was suitable from the standpoint of design of the selectors. All tone frequencies are odd harmonics of 7.5 cycles per second. Therefore, even-order modulation products of the tones do not fall on other tone frequencies. As may be judged by the frequency spacing used, the selectors are tuned sharply, having an average bandwidth of 1.2 cycles per second. A power of only about 0.7 milliwatt is required to close their contacts.

The decision to use a total of 32 signaling frequencies, transmitted four at a time, was based on a number of considerations which may be of interest. First of all, the initial system requirements called for a total of 10,000 possible code combinations. This may seem an unnecessarily large number, since fewer than 100 mobile stations ordinarily operate on the same radio channel in any particular city. However, some of the mobile stations roam from one city to another. The numbers used by these stations, of course, cannot be duplicated in the cities in which they operate. The number capacity of the signaling system should therefore be as large as possible.

Telephone numbers ordinarily consist of a central-office code followed by a 4-digit number. It is desirable that the numbers for mobile-telephone service be assigned on a similar basis, and that the selective-signaling system have a capacity of 10,000 numbers, corresponding to the last four digits of the telephone numbers of the mobile stations.

The following table gives the minimum total number of signaling tones, n, which would be required for various numbers of tones, r, transmitted in each code (or numbers of vibrating-reed selectors per mobile unit):

r	n
1	10,000
2	142
3	41
4	24
5	19
6	17

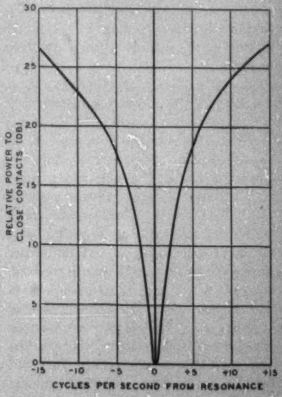
It will be noticed that the value of n is very large when r is small, decreasing rapidly at first as r is increased, then more slowly.

It obviously would be impractical to use a system which required a very large number of different tone frequencies. On the other hand, increasing the value of r means a corresponding increase in the number of vibrating-reed selectors required per mobile station which increases the mobile station cost. It is apparent from the table that little advantage would be gained by increasing the value of r beyond four.

Another factor also entered into the choice of four is the number of selectors per mobile unit. The mobile signal-receiving circuit is subjected to speech and noise signals as well as the signaling tones. It must be designed so that it will not operate falsely on these signals. By requiring that a number of selectors all operate simultaneously to ring the call bell, the probability of false operation is kept small. Tests have shown that no trouble will be experienced with false operation from these causes when four selectors are used.

While a minimum of 24 tones will theoretically produce the desired 10,000 combinations, for practical reasons a larger number is used. It is a system requirement that the signal-sending circuit at the land station be controlled by a telephone dial at the traffic switchboard, and that only four pulls of the dial be required. In order to accomplish this, a register and a translator are used. The dial pulses are counted and registered on the register relays which, in turn, control the translator, which selects the tones corresponding to the desired code and connects them through to the land radio transmitter. Since no simple, orderly relationship exists between the original four-digit number and the combinations of 24 tones taken four at a time, the translator which would be required would be very complicated. On the other hand, if 40 tones were used, they could be divided into four groups of ten, and a tone from each group selected to represent the corresponding digit of the telephone number. The translation problem then would be extremely simple. However, the translation becomes nearly as simple if only 30 tones are used. These are divided into two groups of 15, one group representing the first and second digits of the telephone number, and the other group representing the third and last digits. From each group of 15 tones, it is possible to select 105 combinations of two, of which 100 combinations are used. With this arrangement, translation becomes simple enough so that it may be accomplished

Figure 2. Response curve of typical vibrating reed selector



by using the contacts of the register relays; a separate translator is not required.

A further increase in the number of tones, to a total of 32, was adopted for another reason. The system must be designed so that false signaling does not occur in a mobile station when the land station transmits four tones of which three are the same as three tones of the code of the mobile station in question. The danger of false signaling is greatest when the fourth vibrating reed selector is subjected to two adjacent tones, one being one channel higher in frequency and the other one channel lower. This occurs only in mobile stations which are equipped with two selectors tuned to adjacent channels. Such codes may be eliminated by using two groups of 16 tones, or a total of 32.

Transmission Considerations

The system must be capable of operating over any useful radio circuit. Experience has shown that signaling is reliable, and normally will fail only on a much poorer radio circuit than is useful for speech transmission.

Tests also have shown that, in a properly designed and adjusted system, false signaling is virtually absent. However, there are a number of possible causes of false signaling. In the development of the system, it was necessary to give them careful consideration.

The possible causes of false signaling can be divided into two classes:

1. Those which occur when no signaling tones are being transmitted and thus simultaneously must operate all four vibrating reed selectors in the mobile station in order to produce a false signal.
2. Those which are the most serious when a code having three tones the same as the code of the mobile station in question, is being transmitted.

Causes of false signaling in the first class include noise, speech signals which are received during a call between the land station and another mobile unit, and the occasional transmission of various telephone-plant tones which possibly might contain frequency components corresponding to the resonant frequencies of the selectors in the mobile station in question. Tests have shown that no trouble may be expected from false signaling caused by any of these. Protection against such false signaling results from the fact that the selectors are tuned extremely sharply, so that the probability of sufficient energy falling within the bands of all four selectors to operate them is extremely small. As stated previously, the bandwidth of the vibrating-reed selectors is about 1.2 cycles per second. Figure 2 shows a response curve for a typical unit.

Causes of false signaling in the second class include cross-modulation products of the signaling tones, and adjacent-tone interference. Since the signaling tones are all odd harmonics of a basic frequency (7.5 cycles per second), even-order cross-modulation products always fall halfway between tone frequencies, and therefore would not be expected to cause trouble. On the other hand, odd-order products may fall directly on the signaling frequencies, and thus are potential causes of false signaling. However, tests have shown that there is ample margin against cross-modulation trouble in a well-designed system.

Tests made during the development of the system indicated that the most serious possible cause of false signaling was adjacent-tone interference. It was therefore necessary to give particular attention to this effect. The final system has been designed so as to be virtually free of such trouble.

Figure 2 shows that the steady-state discrimination of a typical selector against an adjacent tone 15 cycles per second away is greater than 25 decibels. Since the signaling-tone level applied to the selectors is normally about 8 decibels more than required just to close their contacts, the tone level would have to increase more than 17 decibels above normal for false operation to occur.

A peculiar type of interference, however occurs in moving vehicles when weak signals are received. Application of the system to date has been on frequency-modulation radio systems in the 150–160-megacycle band. Because of reflection of the radio waves, the signals almost always are transmitted from the transmitter to the receiver along two or more paths. Signals arriving by various paths may combine in or out of phase and thus, as the car moves along, the signal is alternately strong and weak as the path lengths vary. It can be shown that the minimum distance from one point of cancellation to the next is 1/2 wave length. As the car is moving along at about 35 miles per hour, fades can occur at rates as high as 15 per second. When the signal is strong, this fading does not affect the audio-frequency output of the receiver, since, in a properly designed frequency-modulation receiver with adequate limiting, variations in signal amplitude do not appear in the receiver output. However, when the signal is very weak, the limiter becomes ineffective and the audio-frequency signal level varies with signal strength. The rapid fading discussed, produces amplitude modulation of the signal. The result is that each tone has sidebands above and below its frequency. When the fading is at a 15-cycle-per-second rate, there are strong sidebands 15 cycles per second above and below the tone frequency or, in other words, at the resonant frequency of the next higher and lower vibrating-reed selectors. Under these conditions, discrimination of the selectors against adjacent tones is decreased markedly. Tests have shown a considerable decrease in margin against false signaling under these conditions. The interference is worst when the radio circuit is just too poor to be useful for voice transmission.

Adjacent-tone interference effects are most serious when the selectors in the car resonate at the frequency of three of the tones being transmitted, the fourth selector being between two tones 30 cycles per

second apart, 15 cycles per second from each. This can occur only in mobile stations having two adjacent selectors 15 cycles per second apart. Mobile stations having codes of this type occasionally may be signalled falsely, and therefore, as discussed previously, such codes have been eliminated by the use of 32 instead of 30 tone frequencies. Tests indicate that, with the 32-frequency arrangement, false signaling will be very rare.

Land Station Equipment

The selective-signaling circuits at the land station consist primarily of a source of tones of 32 different frequencies; a sender, which combines the functions of the register and translator previously discussed, and which counts the dial pulses and selects the proper four tones; amplifiers for amplifying the tones and precisely regulating their levels; and three transformers combining them on one pair of wires. A block diagram of these circuits is shown in Figure 3. When vibrating-reed signaling is provided on more than one radio channel at the same station, some of this equipment can be used in common for all or several of the channels.

The frequencies of the 32 tones must be held to about one part in 10,000, in order that most of the total frequency tolerance may be assigned to the selectors in the mobile station, where wide temperature variations may occur and stability is difficult to maintain. Suitable facilities are not available generally at the radio stations for readily measuring each tone frequency to the required accuracy. An arrangement therefore has been adopted for the 32-frequency source, which provides all frequencies from a common master oscillator, the frequency of which is checked by comparing the reading of an electric clock, operating from a submultiple of its frequency, with radio time signals or other suitable standards of time. The master oscillator, using a laminated crystal resonating at 1920 cycles per second, drives a series of frequency dividing circuits to produce a 7.5-cycle-per-second square wave which contains all the odd harmonics of the basic frequency. The desired frequencies are all odd harmonics of 7.5 cycles per second, the 47th through 111th harmonics being used. These harmonics are selected by means of two band filters, one passing the 47th through 77th harmonics, the other passing the 81st through 111th harmonics. Slope circuits are provided, so that all harmonics in each group appear at approximately the same level. These harmonics then are amplified and applied to 32 very-sharply-tuned filters, each of which selects one harmonic and rejects all others.

These filters use vibrating reed selectors as their frequency selective elements. The selectors differ from those used in the mobile stations only in their bandwidth, which is much narrower than that of the mobile selectors, and in that they do not have contacts. The selectors are used in bridge circuits which are well balanced to all frequencies in the signaling band, except the frequency at which the reeds vibrate. As a reed vibrates, the motional impedance of the selector unbalances the bridge circuit and causes the particular harmonic of the 7.5-cycle wave to which the selector is tuned to appear at its output terminals. The remaining harmonics are suppressed by at least 30 decibels.

The sender follows conventional telephone practice. The dial pulses from the operator's position are counted and registered on four groups of register relays, one group for each digit. The contacts on the register relays are connected to form two networks. The first contact network selects two frequencies from the 352.5- to 577.5-cycle-per-second group, as a result of registering the first two digits; the second network selects two frequencies from the 607.5- to 832.5-cycles-per-second group, as a result of registering the last two digits.

Each of the four tones selected by the sender is applied to an individual amplifier. Since there is some difference between the levels of the tones from the 32-frequency source, these amplifiers are equipped with automatic-gain-control circuits which regulate the levels of the tone to within ±1/2 decibel of the desired value. The outputs of the four amplifiers are combined through a hybrid-coil network and applied to the input of the land radio transmitter.

Mobile Station Equipment

A simplified schematic diagram of the mobile selector circuit is shown in Figure 4. The four vibrating reed selectors are driven by a common coil and are equipped with contacts which close when the reeds vibrate. The selectors fit into sockets inside the driving coil. The telephone number of the mobile station may be changed simply by plugging in a new set of selectors.

To insure maximum contact reliability, the contact current has been kept small. As a result, the selectors are not connected directly to the call bell but, instead, a d-c amplifier tube is used.

The contact closure of the selectors is not continuous but occurs over a short part of each cycle of vibration. The closure does not necessarily occur simultaneously in all four contacts. Therefore, the network consisting of *C1* through *C4* and *R1* through *R8* is used. Capacitor *C1* charges on closure of selector *S1*. Part of its charge is passed along to *C2* on closure of *S2*, and so on, the voltage finally being applied to the tube. Resistors *R2*, *R4*, *R6*, and *R8* discharge the capacitors in a short time after the selectors stop vibrating. Resistors *R1*, *R3*, *R5*, and *R7* protect the selector contacts by limiting the current through them.

The d-c amplifier tube is a pentode connected in an unusual manner. When the selector contacts open, the section of the tube consisting of the cathode and first and second grids acts as a triode with its control grid at nearly cathode potential. The second grid acts as an anode and its current is fairly large. Thus a voltage drop develops across resistor *R9*, raising the cathode above ground potential. The third grid is at ground potential, and is sufficiently negative with respect to the cathode that the plate current is nearly zero. When the selector contacts close, a positive voltage is applied to the third grid, and the plate draws current, operating the signaling relay. The bell in the mobile station continues to ring as long as the proper combination of tones is being received.

The d-c amplifier circuit was chosen because it is extremely stable. When the circuit is designed properly, using a suitable type of tube, the plate current is nearly zero when the third grid is at ground potential, regardless of wide variations in power-supply voltages.

The physical size of the mobile-station equipment required for reed signaling is considerably smaller than that of the corresponding equipment used in the present signaling system. The components shown in Figure 4 require a chassis area of about 10 square inches. In contrast, the corresponding elements of the present system require about 30 square inches. The volume of the present Western Electric type *38A* radio receiver, which is attributable to the built-in selective-signaling circuit, is about 200 cubic inches. The corresponding figure for vibrating-reed signaling is only about 40 cubic inches.

Advantages of the Reed Signaling System

The following are some of the advantages of the new system:

1. The mobile signal-receiving equipment is much smaller, adding only about 40 cubic inches to the volume of the mobile-station equipment instead of 200 cubic inches. This is a very important consideration since present types of mobile-radio equipment are much larger than desirable, and the selective-signaling equipment is an important element in the over-all size.

2. Less audio-frequency power is required from the mobile-radio receiver. In the new signaling system, about 18 milliwatts is applied to the selector driving coil, as against roughly 150 milliwatts applied to the old-type selective-signaling receiver. Since only about 10 milliwatts are required for talking purposes, the new signaling system permits the use of a radio receiver with smaller audio-frequency power capabilities. This reflects in design on the physical size of the receiver and on the current required from the car battery.

3. The new signaling system has a capacity of 10,000 codes, a much larger number than is available with the old system. As discussed previously, this is of importance because service is given to cars which roam from one radio system to another, and whose numbers may not be repeated, therefore, in any system in which they operate.

4. Only four instead of five pulls of the operator's dial are needed in the new system.

5. The selective-signaling portion of the mobile-station equipment for the new system is less expensive.

6. It is much easier to change codes in the new system, since it only is necessary to plug in a new set of vibrating reed selectors.

Application of Multifrequency Pulsing in Switching

MEMBER AIEE

MULTIFREQUENCY pulsing is a form of signaling with alternating current, which permits the rapid transfer over telephone trunks of the information required to select switch paths in local, toll, and tandem dial telephone systems. The multifrequency pulses consist of different combinations of two, and only two, of six frequencies. These six frequencies are spaced 200 cycles apart, from 700 to 1,700 cycles, inclusive. Each combination of two frequencies represents a pulse, and each pulse a digit. The pulses are sent over the regular talking channels and, since they are in the voice range, are transmitted as readily as speech. There are 15 pairs of frequencies possible from the group of six; ten of them are used for the digits 0 to 9, inclusive, and one each for signals indicating the beginning and end of pulsing. The remaining three possible pairs are available for future requirements.

The multifrequency system is arranged so that if more than two frequencies are received by the equipment, the operator who is setting up the connection receives a flashing cord lamp; then she must release the connection and start making the call over again in accordance with her instructions.

The first multifrequency pulsing system was installed at the toll board in Baltimore, Md., to permit the toll operators to complete calls to local crossbar offices without the aid of another operator, and without the use of senders in the toll office. Multifrequency pulsing next was used in connection with the new toll crossbar office installed in Philadelphia, Pa. In this installation calls were received over toll lines from distant points, as well as from switchboards within the city, by means of the multifrequency pulsing system. Today, installations of multifrequency pulsing arrangements are being made in many cities throughout the United States.

Applications of Multifrequency Pulsing

In applying multifrequency pulsing to the telephone plant, it must be kept in mind that the signals used in completing a normal connection in any of our dial telephone systems conveniently fall into two classes: supervision, and pulsing. Supervision includes the connect and disconnect signals going toward the called end, and the "on" and "off" switchhook signals going toward the calling end. The supervision signals can be used under certain conditions for other purposes; for example, to control the start of pulsing, and to recall an operator who may have been assisting in the establishment of the connection. The supervision channel must be ready at once to transmit signals, and, therefore, the supervision signaling equipment is provided individually to the trunk. On the other hand, pulsing signals are required only to set the switch paths and are sent toward the called end. Once the switch paths have been set, there is no longer any need for the pulsing channel, so the use of pulsing signals is limited to the time during which the connection is being established. Accordingly, the equipment used for pulsing can be detached from the connection as soon as it has been set up. In the case of multifrequency pulsing, therefore, the pulsing means are detached from the connection at both ends of the circuit as soon as the switching paths have been established.

OVER-ALL PLAN

The multifrequency pulsing system consists of:

1. The signaling current supply units and distribution arrangements with suitable protection and alarm features.
2. The signal transmitters, either manual multifrequency keysets or dial system multifrequency pulsing senders.
3. The signal receiver connected to the incoming sender or register.
4. The necessary additional maintenance facilities.

One arrangement of the system components for pulsing on a trunk between manual and dial system offices is shown in Figure 1. A local manual, dial system "A," or toll switchboard equipped with multifrequency key pulsing, is shown connected by a direct trunk arranged for multifrequency pulsing to a crossbar office equipped with incoming multifrequency pulsing senders. When an outward operator at a manual switchboard, as shown in Figure 2, handles a call which can be completed through the crossbar office, the first action is to connect a cord circuit to the trunk with the "talk" key operated and operate the *KP* (key pulsing) button of the keyset. The operation of the *KP* key operates a relay that transfers the cord from the telephone set to the keyset, lights a positional *KP* lamp, and prepares the keyset circuit to send the key pulse signal over the trunk as soon as the distant end signals that it is ready to receive pulses. Connection of the cord to the trunk gives a connect signal to the distant end which returns "off-hook" supervision to delay pulsing until a sender is found. When the sender at the distant end has been found, and the pulsing path has been completed, the supervision is changed to "on-hook" as a start-pulsing signal. This causes the *KP* pulse signal to go out automatically and lights the positional sender lamp.

Paper 49-101, recommended by the AIEE communication committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted November 16, 1948; made available for printing December 22, 1948.

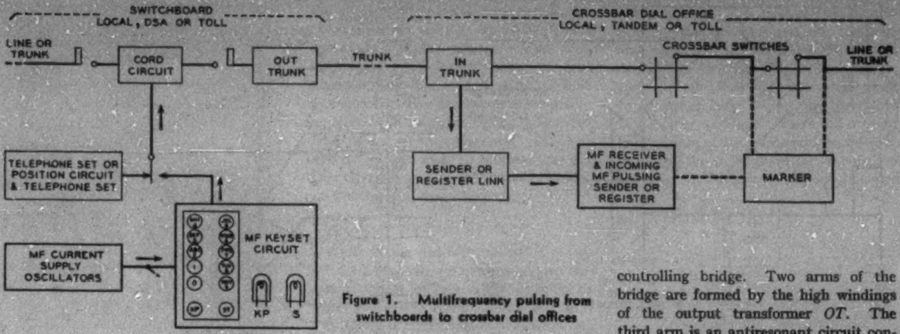

Figure 1. Multifrequency pulsing from switchboards to crossbar dial offices

Receipt of the *KP* signal at the distant end prepares the multifrequency receiver to accept the digits that are to follow. The operator may begin sending the digits of the called number as soon as the positional sender lamp is lighted. She will do this by pressing one button for each digit. Following the last digit, she presses the *ST* (start) button to indicate the end of pulsing. In addition to informing the distant sender that no more pulsing signals are coming, the operation of the *ST* key disconnects the keyset from the cord, reconnects the telephone set under control of the "talk" key, and also extinguishes the *KP* and sender lamps.

If the operator presses two buttons simultaneously, or if she presses the *KP* key after the positional sender lamp lights, a reorder signal is received from the distant end causing the cord supervisory lamp to flash, requiring the operator to release the connection and start the call over again.

Other Applications

In addition to the use of multifrequency pulsing from manual positions to local, toll and tandem crossbar offices, there is also a wide use of multifrequency pulsing between the incoming senders at the toll crossbar-switching offices and the local crossbar offices. In this case, the multifrequency pulses are sent out by a sender, instead of by a keyset. The rate of sending averages about seven digits per second, instead of the two digits per second normally keyed by the operators.

The toll crossbar and certain local crossbar offices are equipped to transmit, as well as receive, multifrequency pulses. A further application to toll switchboards has resulted in the use of multifrequency pulsing senders which will receive multifrequency pulses and transmit dial pulses. This arrangement is used to set up connections to the step-by-step type of office.

Multifrequency Current Supply

The current supply circuit consists of two groups of bridge-stabilized oscillators. Each oscillator group normally supplies one-half of the office load, but each oscillator group is capable of carrying the whole office load if failure occurs in either group. Each group consists of six oscillators operating at the frequencies 700, 900, 1,100, 1,300, 1,500, and 1,700 cycles respectively. The oscillator design is such as to provide constant frequency and amplitude output for normal variations in power supply and output load.

Description of Oscillator

One of the bridge-stabilized oscillators is shown schematically in Figure 3. It consists of a high-gain pentode vacuum tube *V*, operated as a class *A* amplifier, together with a frequency- and amplitude-controlling bridge. Two arms of the bridge are formed by the high windings of the output transformer *OT*. The third arm is an antiresonant circuit consisting of retardation coil *L* and capacitor *C* connected in parallel, while the fourth arm is a resistance *R* having a value slightly less than the impedance of the antiresonant circuit at the oscillator frequency. Part of the retardation coil is shunted by a thyrite varistor *VR*, whose impedance is responsive to amplitude variations. For low voltages, the varistor has a very high effective resistance, but its value decreases rapidly as the amplitude of the voltage is increased. Taps are provided to allow adjustment of the output voltage at the time of installation.

For the normal frequency F_0 and output voltage E_0, the impedance of the antiresonant network is resistive and slightly larger than the resistance arm of the bridge. Thus, a small voltage unbalance is applied to the grid of the *V* tube, and the oscillations are sustained. For frequencies above or below F_0, the antiresonant circuit reactance becomes capacitive or inductive, respectively; the magnitude of the reactance depending on how far the frequency shifts from the antiresonant frequency. These effects of frequency upon the phase angle of the impedance near antiresonance, and of amplitude upon the magnitude of the antiresonant impedance, are used to stabilize the frequency and amplitude of the oscillations.[1] The frequency control exerted by the tuned circuit depends upon the fact that the phase shift of the amplifier tube must be equal and opposite to that through the bridge circuit.

Figure 2. Outward operator at toll switchboard

Coding and Distribution of Frequencies

The output frequencies of the six oscillators are distributed to keysets, located in the various switchboard positions, and to outgoing senders in the switching equipment. A typical distribution plan is shown in Figure 4. The signaling frequencies have been desig-

nated 0, 1, 2, 4, 7, and 10 for the 700, 900, 1,100, 1,300, 1,500, and 1,700 cycle frequencies, respectively. Frequencies 0 to 7 are used for the digit codes while frequency (10) in combination with the (2) or (7) frequency is used for special signals. The code which is referred to as an "additive code" is shown in Table I. Except for 0, *KP*, and *ST*, the frequency designations add to give a sum equal to the digit being transmitted. This feature of the code assists the maintenance forces when clearing troubles which may occur.

Alarm Features

Each group of oscillators is equipped with various types of alarm features. To guard against failure in the output, sensitive voltage relays are connected across the output circuits of the oscillators in pairs in differential relation. Therefore, if the output voltage of one individual oscillator departs more than 1.5 decibels from the output of its mate, the voltage relay operates and causes the load to be transferred automatically to the other oscillator group, and in addition sounds an alarm. Trouble grounds and power failures also are guarded against, and necessary alarms are given. In addition, an arrangement is provided whereby the transmission of number information, by sender equipment, is halted during the transfer interval and either transmission is resumed when the transfer is completed, or a reorder signal is given to the originating operator.

Figure 5 shows a typical installation of multifrequency supply oscillators, together with alarm relays.

Table I. Coding of Frequencies

Digit	Frequencies in cycles per second	Frequency designations
1	700+ 900	0+ 1= 1
2	700+1,100	0+ 2= 2
3	900+1,100	1+ 2= 3
4	700+1,300	0+ 4= 4
5	900+1,300	1+ 4= 5
6	1,100+1,300	2+ 4= 6
7	700+1,500	0+ 7= 7
8	900+1,500	1+ 7= 8
9	1,100+1,500	2+ 7= 9
0	1,300+1,500	4+ 7=11
KP	1,100+1,700	2+10=12
ST	1,500+1,700	7+10=17

Multifrequency Signal Receiver

The signal receiver is shown in Figure 6, and a simplified circuit schematic diagram is shown in Figure 7. Starting at the input from the line, there is: a shielded repeating coil, a gain adjusting pad, an impedance-controlling resistance, and a volume-limiting amplifier. The circuit branches at the output of the limiter, one branch going through the six channel filters, detectors, and relays, and the other going through a high-pass filter, detector, and a low-pass filter to the signal present *SP* relay. The operation of these relays controls the registration of the received signals in the sender which is associated with the receiver.

Operation of Receiver by Key Pulsing Signal

When the receiver is first connected to the line, possible false operation by speech prior to the start of pulsing is prevented by means of a slightly different relay arrangement from that shown in Figure 7. With this arrangement, it is necessary that the *KP* signal operate channels 2 and 10, and that all other channels remain unoperated, for a period of at least 55 milliseconds. At the end of this interval, the receiver is changed to the condition shown, and is prepared to accept the digits that are to follow.

Operation of Receiver by Digit Signals

When the receiver is in the pulsing condition, the two signal frequencies applied to the input are amplified or limited depending upon the received-signal power. The frequencies are selected then by the two appropriate channel filters and are detected. In the absence of incoming signals, plate current normally flows in the detectors. The presence of a signal biases the tube to reduce this current to a low value, which is more or less independent of the strength of the signal. The channel relays are energized by current from a battery through the *P* windings, and are prevented from operating by the plate current flowing in the *S* windings, which produces a flux which opposes and balances that caused by the current in the *P* winding. Consequently, when plate

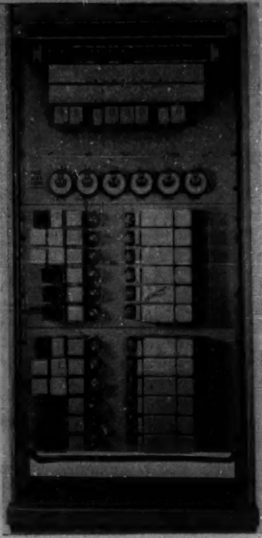

Figure 5. Oscillator and alarm unit

current is reduced sufficiently, the relay will operate. When the back contact of a relay is opened, ground is removed from a resistance and battery to reduce the screen voltage of the tube, which in turn further reduces the plate current, thereby producing a "snap" action to insure rapid and positive operation of the relay armature to the front contact. The reduction in plate current by this means is sufficient to prevent the release of the relay, even though the signal is subsequently removed. Thus, the relay is locked in the operate condition until the current in the *P* winding is interrupted by the sender after the registration has been completed.

Both signal frequencies enter the signal-present *SP* circuit and pass through a high-pass filter, the purpose of which is to reduce the effects of low-frequency noise, and operate the detector. The low-pass filter in the output of the detector serves to limit the fluctuations in the detector output, which occur at a frequency equal to the difference of the input frequencies, and to delay the operation of the signal-present relay. The front contact of this relay controls the operation of the sender to prevent duplicate registration of a digit in case a signal is unduly prolonged, and causes ground to be applied to the operate or *P* windings of the channel relays. This operation is delayed to reduce the effect of transients produced in the channel filters, which otherwise would operate falsely other channel relays. The back contact momentarily alters the grid biases of the limiter and signal-present detector to reduce effectively the relative sensitivity of the signal channels to avoid false operation by transients. The sensitivity is restored to normal as the capacitor associated with the back contact of the relay becomes charged.

CODE SELF-CHECKING FEATURE

Noise may cause false operation of one or more channels, or more than two frequencies may be received if an operator falsely operates two keys simultaneously.

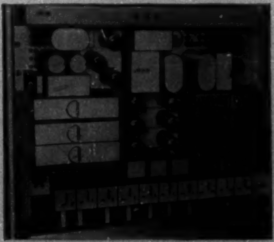
Since each digit consists of exactly two frequencies, a check can be made that a bona-fide signal has been received. This is done as follows:

> Removal of ground by the back contact of a channel relay permits current to flow through a resistance to the relays *CK1*, *CK2*, *CK3*, and the current through the operate windings of these relays is proportional to the number of channel relays which are operated. The non operate bias of the *CK* relays are adjusted so that none will operate with a single channel relay operated, *CK1* and *CK2* will operate with two channel relays operated, and all three will operate when three or more channel relays are operated. These relays control the operation of the sender in such a way that the operation of a single channel relay is ignored, two channel relays operated permits registration of the appropriate digit, and with three operated the sender is informed that the signal is incorrect, where upon a reorder signal is transmitted to request retransmission of the number.

TRANSIENT PROTECTION BY TIMING

The receiver is required to operate on signals transmitted over lines which differ in attentuation and which have attenuation distortion or "twist." This requires that each channel shall be sufficiently sensitive to operate when the attenuation is a maximum, and not falsely operate on the filter transients when the attenuation is a minimum. To illustrate the significance of this problem and the methods used to satisfy the requirements, we will employ the formulas for the transient response of an ideal band-pass filter given by Guillemin,[3] and use only the envelopes of the filter response. When the applied frequency is at the midband frequency of the filter, the envelope of the response to a sine wave of unit amplitude is given by

Figure 6. Multifrequency signal receiver unit



$$E(t)=\frac{1}{2}+\frac{1}{\pi}Si\left[\frac{w}{2}(t-t_d)\right]$$

where

$$Si(x)=\int_0^x \frac{\sin x}{x}dx$$

$$w=2\pi(f_2-f_1)$$

and f_2 and f_1 are the cut-off frequencies of the filter and t_d is the delay time of the filter. When the applied frequency is outside the pass band of the filter, the envelope of the response is given by

$$e(t)=\frac{1}{\pi}\frac{w}{\omega_m}\frac{\sqrt{\omega_m{}^2\cos^2\theta+\omega^2\sin^2\theta}}{\frac{\omega^2}{\omega_m{}^2}-1}\cdot\frac{\sin\frac{w}{2}(t-t_d)}{\frac{w}{2}(t-t_d)}$$

$\omega_m=\omega_1+\omega_2/2$ is 2π times the midband frequency, and θ is the phase angle of the applied wave. A plot of these equations is shown in Figure 8 for the case of a filter with a pass band 100 cycles wide and a midband frequency of 900 cycles. Since the results obtained with the filters actually used differ materially from those obtained with an ideal filter for times below 10 milliseconds, these portions of the curves are not shown. The top curve corresponds to an applied frequency of 900 cycles, and the bottom curve (drawn on an expanded amplitude scale) corresponds to an applied frequency of 700 cycles and a phase which yields the maximum amplitude. t_d was chosen arbitrarily as ten milliseconds. The first maximum of $e(t)$ is approximately 21 decibels below the final value of $E(t)$. Since we may have two frequencies present in channels adjacent to the one under consideration, the transient discrimination is 6 decibels less or only 15 decibels. Since the wanted signal does not reach its final value until about the time that the unwanted transient reaches its first minimum, it should be possible to increase the discrimination by about 9 decibels if operation of the channels is prevented until after the first minimum of the transient has occurred. This is ac-

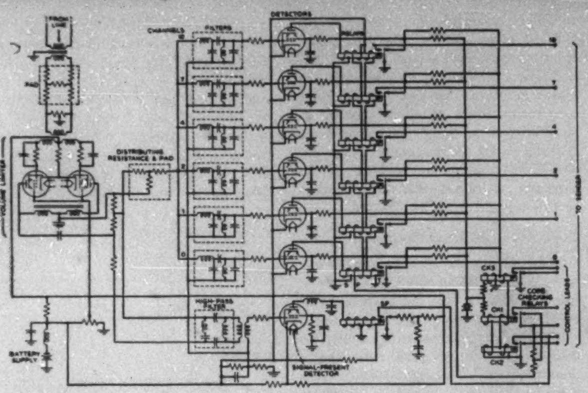


Figure 7. Multifrequency signal receiver, schematic diagram

complished by delaying the operation of the signal-present relay by means of a low-pass filter. To obtain this advantage, the time of occurrence of the minimum response must be the same in all channels. Reference to the foregoing formula shows that this requires the same bandwidth in cycles, and the same delay time for all the channel filters. With these conditions met, approximately equal discrimination, transient or steady state, is obtained with equal spacing of signal frequencies.

Transient Protection by Limiting

Additional protection against false operation by transients is secured by the use of a peak-limiting amplifier which acts as a linear amplifier for inputs up to a certain definite point called the point of limit; above this point the output is held constant. With a 2-frequency input to the limiter, it is necessary that the point of limit be at least six decibels above the single-frequency input which is just sufficient to operate a channel detector. If there is a difference in amplitude of the two input frequencies, the point of limit must be raised still further. For the case of n applied frequencies, let $V_1, V_2 \ldots V_n$ be the voltage amplitudes at the output of the limiter without limiting, and let V_L be the output voltage when limiting occurs. The point of limit is defined by

$$V_1+V_2+\ldots V_n=V_L$$

If L is the loss in decibels introduced by the limiter above the point of limit, we have

$$(V_1+V_2+\ldots V_n)10^{-\frac{L}{20}}=V_L$$

Without loss of generality, we can assume

$$V_1\leq V_2\leq\ldots\leq V_n$$

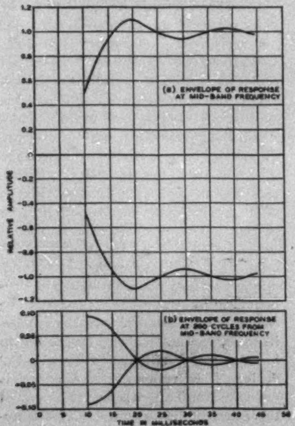
To insure operation on the minimum amplitude when limiting occurs, we must have

$$V_1 10^{-\frac{L}{20}}\geq V_0$$

where V_0 is the voltage required to just operate a channel detector. M is the margin in decibels between the just-operate voltage and the point of limit, measured with a single frequency, or

$$V_0 10^{\frac{M}{20}}=V_L$$

Figure 8. Envelopes of response of band-pass filters to applied sine wave



From the preceding equations we obtain as a condition for operation

$$\frac{V_1 10^{\frac{M}{20}}}{V_0+V_2+\ldots V_n}\geq 1$$

or

$$M20\log_1\geq_0\left(1+\frac{V_2}{V_1}+\ldots\frac{V_n}{V_1}\right)$$

Thus, the margin between "just limit" and "just operate" is determined by the number of frequencies, and is a function of the ratios of the larger voltages to the smallest one. For the case of $n=2$, M is shown in Figure 9 as a function of the difference in decibels of the tow voltages. With a nominal margin of 12 decibels, the maximum difference between two voltages is about 10 decibels.

When allowance is made for variations in components of the frequency sources and the receivers, the following operating characteristics are obtained:

Digit and ST signal duration, 27 milliseconds or greater.

KP signal duration, 55 milliseconds or greater.

Interval between signals, 20 milliseconds or greater.

Maximum receiver input power, 2 decibels above one milliwatt at each signal frequency.

Minimum receiver input power, 27 decibels below one milliwatt at each signal frequency, provided the difference in power between the two frequencies making up the signal does not exceed 6.5 decibels.

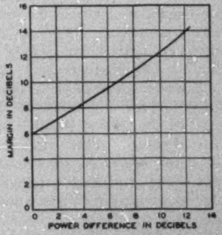


Figure 9. Required margin between "just limit" and "just operate" as a function of the power difference of two frequencies

Trackless Trolley Operation in Rhode Island

H. R. BLOMQUIST
MEMBER AIEE

Synopsis: This paper attempts to set forth the knowledge gained in operating a growing trackless trolley system over a period of 17 years. It in no way is intended to prove that the trolley coach is a cure-all for transit ills. Unbiased transit experts recognize the need for all types of vehicles in the industry: "A place for every vehicle–every vehicle in its place." We subscribe fully to this doctrine.

THE United Electric Railways Company serves a population of 594,000 persons living in 16 contiguous cities and towns covering an area of 334 square miles. It operates on 390 miles of road, and in 1947 operated 18,000,000 vehicle miles, carrying 142,000,000 passengers.

It was on this property that trackless trolley operations in New England was inaugurated at the very depths of a severe business depression. Earnings on the United Electric Railways Company property had dropped 28 per cent since the peak in 1926, and the transit industry generally was experiencing hard times. Ways and means of remaining solvent were needed sorely by the industry, as competition by private automobiles continued to cut deeply into the earning power of mass-transportation organizations.

In searching for a means to stem the tide of diminishing revenue, the company management decided to experiment with the trackless trolley. It was hoped that this modern-type of vehicle, through stimulated riding and reduced operating expenses, would stop the downward trend of earnings.

A few properties were already operating trackless trolleys, but little was known of their drawing power or operating problems. However, it appeared to incorporate in one vehicle the advantages of both the street car and the motor bus without their inherent disadvantages. It rolled on rubber, had maneuverability, smooth acceleration, good lighting, and operated quietly and without odor.

The Brook–Weeden Line, operating in Pawtucket, R. I., was selected as the "guinea pig." This was a cross-town street-car line about five miles long, operating between the east and west sides of the city by way of the downtown area, and would require only five vehicles. The route was primarily in a well built-up residential section and was earning about 41 cents per vehicle mile, as compared to the rail system average of 39 cents. The operation of this first trackless trolley line was watched with keen interest by the management, and the financial results of the first year surpassed their most optimistic hopes.

A study of the operating results indicated that substitution of trackless trolleys for street cars had resulted in an 11 per cent increase in revenue. The cost of maintaining the trackless trolley compared favorably with that of the motor bus, and no difficulties were encountered in keeping them in operation. The use of the trolley coach in a very short time had won enthusiastic supporters among the public and within the company.

From this inauspicious beginning has grown one of the largest trackless trolley systems in the world. Today it includes 80 miles of overhead and 330 vehicles which operate 8,500,000 miles per year, carrying 85,000,000 passengers. As a result of 17 years of experience in construction and operation, there have been developed many essential methods and techniques, some of which are today common to the industry, but some of which still are unique on this property. These cover such functions as vehicle storage, overhead construction, and vehicle maintenance.

Vehicle Storage

In spite of the rigors of New England winters, a decision to store trackless trolleys out-of-doors was reached in the early stages of development and has been adhered to through the years. It has proven to be a most suitable and economical procedure. There are two depots on the property today, out of which operate all of the trackless trolley lines. Typical of these vehicle storage areas is one at the Elmwood station. It occupies a corner lot 200 feet wide by 575 feet long, paved with a 2 inch sheet of asphalt on a 4-inch layer of crushed stone over a 6-inch banked-gravel base. The area is fenced on one side and an end, and is well illuminated with mercury-arc floodlights.

Vehicles are stored in 17 lanes parallel to the long dimension with 3-foot aisles between adjacent rows. Two 10-inch fire lanes are provided, at right angles to each other extending across the center of the lot, so that when the area is filled there are actually four blocks of vehicles

Figure 1. Trackless trolley storage area at Elmwood

Paper 49-104, recommended by the AIEE land transportation committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted November 16, 1948; made available for printing December 22, 1948.

H. R. Blomquist is with the United Electric Railways Company, Providence, R. I.

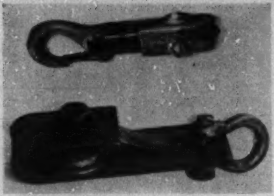

Figure 2. Rollers for tangent construction (above). Rollers for angle construction (below)

separated from each other by these fire lanes.

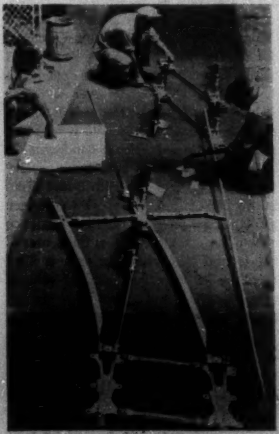
Readily accessible fire-fighting equipment, in standard hose houses as specified by the Fire Underwriters, is provided at several locations along these fire lanes. Overhead trolley wires are located so that each pair of wires serves two parking lanes, thus reducing to a minimum the overhead construction required, without hampering operations. The entire area contains 115,000 square feet and accommodates 185 vehicles with ample room for servicing.

The cost of this parking area over and above the land is approximately $80,000, broken down as follows:

Paving ($2.50 per yard), $32,000
Fire-fighting equipment, $5,000
Overhead construction including feeder, $40,000
Lighting, $3,000

Thus the cost of the area exclusive of land is equivalent to $432 per vehicle. Of the $40,000 for overhead construction, approximately one-half is for feeder. This is on account of the fact that the feeder requirements for an area of this sort are very heavy during the winter months, as the auxiliary electric heaters in the vehicles are used for warming up the coaches before they go into service. These auxiliary heaters are rated at 15 kw, so that with 185 vehicles stored the connected heater load is 2,775 kw.

Figure 3. Shop assembly of trackless-trolley intersection



Overhead Construction

The trackless-trolley overhead system is one of the most critical parts of the entire plant. It is vitally important that these structures be erected economically and in such a manner that they will not be eyesores. Rubber-tired equipment has permitted mass-transportation vehicles to deviate from their former routes along main traffic arteries, and to wend their way into the very heart of residential areas. Here neatness of overhead lines is a must.

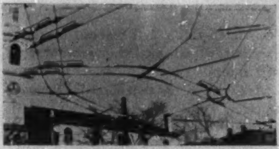


Figure 4. Trackless-trolley overhead—North Main and Waterman Streets, Providence, R. I.

1. The poles must be raked so that when load is applied they all shall be in the same line.
2. The span wires shall be sloped no more than is necessary and all in the same plane.
3. The contact wires on tangent construction shall be in a perfectly straight line.
4. Special work at intersections shall have no more supporting wires than is necessary.

These four items are the criterion of good overhead design and construction, and our methods were developed with these objectives in mind.

The construction of trackless trolley overhead can be broken down into five phases:

1. Installation of poles.
2. Installation of tangent spans.
3. Installation of curve segments.
4. Stringing trolley contact wire.
5. Installation of special work at intersections.

There have been developed special methods and tools for each of these phases which have reduced substantially the cost of installation, and at the same time result in an overhead structure which has been received very favorably by the community and is acceptable in residential area.

Poles were formerly ground-braced with heel and toe planking, the installation of which was time-consuming and difficult. When load was applied to the pole, the base invariably would shift in the ground because the pole was not bearing firmly against the planking. The degree of shift varied from pole to pole, resulting in an irregular lining up of poles. In order to eliminate this irregularity, it was decided to ground-brace poles with poured concrete and to do it in such a manner as to permit the pole to be readily removable in case of replacement. The pole is placed in the hole, the position and rake being adjusted and controlled by means of three wooden wedges placed around the pole. Two flat spades with long handles are then placed radially at the bottom of the hole, about 90 degrees apart at back of pole. Concrete is poured back of spades to a depth of one foot, and gravel is placed around the street side of the pole, watered and tamped. Spades are then removed, the hole filled with gravel to a point about 16 inches from ground grade, and wedges removed. The two spades are placed back in the hole on the street side, concrete poured at the front of the pole, and gravel placed at the rear. The spades are removed, and the remainder of the hole is filled with gravel, watered, and tamped. The pole is permitted to stand for about a week before any load is applied. The use of wedges for supporting pole during the setting operation has reduced the pole crew to seven men, and this crew with a foreman can set ten poles per day, including digging.

In order to speed up the installation of span wires in tangent areas without sacrificing the appearance of the finished job, the span wires are preloaded to get the correct length and height. We have standardized on a span-wire slope of one foot in eight feet, and the engineering department prepares a cross-section drawing showing the height of the point of attachment to the pole for each street width on the line. The first tangent span at any particular street width is installed by hanging two weights of 100 pounds each on the span wires, one at the point selected for the outbound pair of trolley wires and one at a point corresponding to the inbound trolley wires. The span wire is attached to the poles at the elevation specified by the drawing and then tensioned to 800 pounds.

The span wire is made fast to the pole, and the weight is removed. This span wire is now ready, properly tensioned and at proper height above the highway. It of course would be possible to repeat this performance at each span wire location, but this would be slow and cumbersome. To expedite the operation, a measuring device is used, consisting of a 50-pound weight fastened at the end of a telescopic rod, the length of which is adjustable. This measuring device is hung at the center of the span wire which has just been installed by the preloading method, and the length of the rod adjusted until the weight swings just clear of the roadway. We now have our measuring stick to use on all other spans installed along the line until a different road width is reached. This measuring device is hung at the center of each succeeding span, and the span wire tensioned until the weight swings clear. This method permits high-speed installation of all span wires in tangent areas. When a new street width is reached, the first span is again preloaded, the measuring device then is reset and used on the succeeding spans. The possible error created by the fact that some spans are from wood to wood, some from steel to steel, and others from steel to wood, is so slight that it has no apparent effect on alignment to completed line.

Because of the recent improvements in segment design, such as smooth underrun and long runners permitting high-speed operation, we use them almost exclusively for low-degree turns as well as at corners. Any curve calling for segment installation is covered by an engineering drawing, which shows not only the elevation of pole attachments and span wire tensions, but also shows the exact location of the segment with respect to two reference lines at right angles, selected so that they can be identified easily in the field. The line crew, using these reference lines, mark on the street the exact spot over which the segment is to be located, and the segment without runners is then installed by plumbing-down to this point.

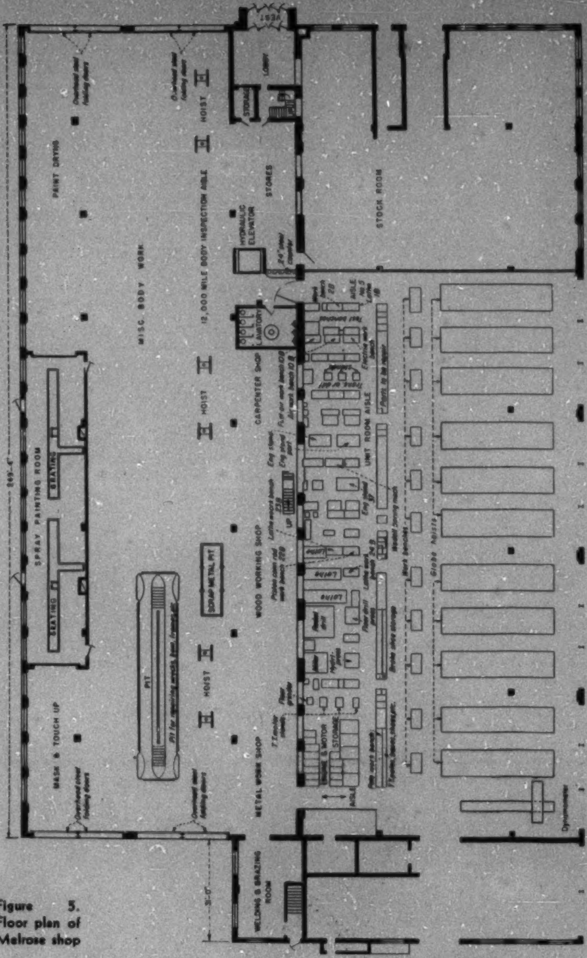

Figure 5. Floor plan of Melrose shop

The method of stringing trolley wire has been improved drastically by the use of a simple device designed in our own shops. This device, which we call an "anti-friction roller," consists of a small grooved wheel mounted in the hook of a J-shaped bronze casting about 1/2-inch wide and 3-inch long over-all. A spring clip closes in the top of the hook, and a snap hook fastened to the top of the *J* permits the device to be hooked onto a span wire. This roller is used on all spans in tangent areas where no side pull is developed when trolley wires are tensioned.

A similar roller, differing only in that it is larger and heavier, is used at segments and any other angle points. This angle roller is equipped with a length of wire cable and a 3-bolt clamp, so that it may be clamped to the segment-supporting wire or span to prevent any possibility of side slip.

After all span wires and segment plates have been installed on a new line the angle rollers are clamped in place at all angle points, and the job is ready for wire stringing.

A truck used in stringing wire is provided with a special wire reel stand equipped with a water-cooled brake drum. The wire is fed up over a tower truck following directly behind the wire truck; the tangent antifriction rollers are snapped onto the trolley wire and then onto the span as the trucks move along, and the contact wire is hooked into the rollers already in place at angle points. Ordinarily, the trolley wire for the entire line is strung before the tensioning is done. This is possible because the use of rollers reduces the friction to a minimum. By this method it is possible to string eight miles of wire per day with one crew. It is this speed which makes necessary the water-cooling of the brake drum on the reel stand. With the wire all in place, the tensioning is completed. Although long lengths are tensioned in one operation, it has been found that no more than three per cent of the tension is lost from one end of the line to the other.

The hangers and ears now are installed; the wire is removed from the rollers in tangent sections and is clamped in the trolley cars. This leaves only the angle rollers to be removed. The segment runners are installed, a chain jack is fastened to the pull-off wire, and loop is fastened between jack and trolley wire at the center of the segment. The jack is pulled up to remove the load from the angle roller. This is unhooked, and the jack is slacked off so that the trolley wire approaches the runner. The wire is guided by means of a Stillson wrench so that the groove is in proper location, and one of the segment clamps is tightened over the trolley wire when it is positioned properly. The loop is slipped over far enough to engage a second clamp, and this process continues until the loop is clear of the runner. The loop is then removed and placed on the opposite side of center clamp. The process is repeated until all clamps on this side are securely fastened to wire.

Engineering drawings of all junction points are provided, showing the exact location of all poles and special work, together with the elevations, tension, and length of all supporting wires. The intersection is assembled on the shop floor with all wires cut to length and tagged for identification. The material is then erected in the field by plumbing the location of each unit to a mark on the street. The preliminary shop work greatly expedites the field construction.

When the new line has been completed, a trial trackless-trolley run is made in order to check the need for any immediate adjustments. It is then turned over for regular operation and run for about a month before the final dressing up is made. At that time all trolley wire in tangent sections is lined up by means of a surveyor's transit; locations of all segments and special work is checked, and all supporting wires are clipped to proper length and the ends lashed.

A typical construction project was the erection of the trackless-trolley overhead for the Dyer–Plainfield Lines in 1946. It consisted of 177 solely-owned poles, 3.24 miles of 2-way overhead with 4 intersections, each having a leading switch, trailing switch, and crossover; 62 curve segments ranging from 2 degrees to 45 degrees, 2 terminal loops each made up of 8 curve segments and 2.82 miles of 500,000-circular-mil feeder cable. The number of poles set is low because the remaining poles were jointly-owned with the power company and/or the telephone company, and are not included in the analysis. The feeder installation is low, as a considerable part of the positive feeder used on the original rail lines was available and in place.

Figure 6. Portion of unit repair section at Melrose shop

The cost of the entire installation as described is shown in Table I, and is equivalent to $12,955.46 per mile.

Table I. Cost of Installation

	Labor	Material	Total
Poles......	$ 4,465.09..	$ 5,584.63..	$10,049.72
Feeder.....	5,063.96..	4,413.66..	9,477.62

Total......	$16,989.76..	$24,985.95..	$41,975.71

Vehicle Maintenance

One of the important decisions which had to be made when trackless trolleys became a part of our operations was that pertaining to vehicle maintenance. Should the vehicles be maintained by the rail mechanical department or the bus mechanical department? There were only a few companies operating trolley coaches at the time, and no pattern had been established which could be used in the solution of the problem. After considering local conditions and the vehicle itself, it was decided that they should be maintained by the bus mechanical department. The men in the department were schooled in the fundamental principles of electricity and electric motors in order that they might have some idea of the functions of the various parts of the propulsion and control equipment. This schooling, together with instructions from the manufacturers of the electric equipment, proved to be invaluable training for the bus mechanical staff.

The experience of the passing years has proved our original decision an excellent one. Some years before the inception of trolley coaches, the bus mechanical department had developed a system of protective maintenance for motor busses in which the frequency of inspections and maintenance of each part of the vehicle was based on mileage. The life of each part in miles had to be established by experience, but these had been pretty well-determined for motor busses. It was a simple matter, therefore, to set up a maintenance schedule for trackless trolleys for everything except the electric equipment. The chassis, steering mechanism, axle, and so forth were comparable to motor-bus equipment, and the maintenance of these parts was set up on the same mileage schedule. Temporary mileages were established for the propulsion and control equipment with the help of the manufacturers, and these have been adjusted as found necessary by operating experience.

The frequency of road failures served as an excellent criterion to determine the need for changes. Seventeen years of operations have served to stabilize maintenance mileages, and today our entire program is based on inspection and maintenance at 2,000 miles, 6,000 miles, and 24,000 miles. Obviously the higher mileages must be multiples of the lower mileages.

The 2,000 mile inspection includes the following operations:

Check motor brushes on traction motor, auxiliary motor, and auxiliary generator.
Drain air tanks, air system, and water separator.
Lubricate rear end.
Spray springs, rods, and so on, under vehicle at points of wear.
Check sanders.
Check wheel nuts.
Check for broken springs.
Test and adjust brakes.
Check all contact tips.
Check lights.

The 6,000 mile inspection consists of the following operations:

All work performed at 2,000 miles.
Clean brush holders and insulators.
Align front wheels.
Check for charged body.
Check switches and heaters.
Check points and adjust voltage regulator.
Check and clean auxiliary generator.
Check air cleaner.
Focus head lights.
Blow out motors and control cabinets with compressed air.

The 24,000 mile inspection includes the following:

All work performed at 2,000 miles and 6,000 miles.
Change retrievers and grease trolley base.
Check pole tension.
Change compressor oil and air cleaner.
Oil windshield wiper, door engine, and damper cylinder.
Change door air cleaners.
Change brake valve head.
Grease wheel bearings.
Adjust wheel stops.
Grease motor bearings.

At 240,000 miles, the propulsion motors are removed for complete overhaul, including dipping and baking of armature.

Busses are painted on a regular schedule which has been established through the years, and which has proved to be very satisfactory. This schedule consists of painting the outside, from the windowsill down, every six months; the entire outside every 12 months, and the inside every three years. This maintenance and paint schedule has resulted in excellent performance and appearance.

In 1947 there were 1,137 roadcalls because of electrical failures in 6,224,565 miles, which is equivalent to 5,476 miles per roadcall, and 3,713 roadcalls because of both electrical and mechanical failures, or 1,676 miles per roadcall. The direct charges for labor and material amounted to 2.81 cents per mile, broken down as follows:

Motors	0.13¢
Electric system	0.31
Line breaker	0.01
Air system	0.15
Control equipment	0.22
Overhead system	0.38
Rear end	0.21
Front axle	0.07
Steering post	
Brakes	0.28
Chassis	0.28
Body	0.56
Painting	0.16
Accidents	0.05
Total cost	2.81¢

Operating Results

The year 1948 saw the end of rail operation on the United Electric Railways Company property. From an all-rail system in 1921, it has been converted to a 100 per-cent rubber-tired system over a period of 27 years. Today the property consists of approximately one half motor busses and one half trackless trolleys. The majority of the urban lines are trackless trolley; the suburban lines, motor bus. This has proved to be, in our case, a very satisfactory balance. In only one instance have we found it necessary to second-guess a vehicle changeover, every other case having proved itself in actual operation over the years.

Trackless trolley operation has become a vital part of our system, as it earns 60 per cent of the revenue and accounts for 51 per cent of the vehicle mileage. As previously has been stated, the revenue of the original trackless trolley line increased about 11 per cent after the line was converted. This increase has been substantiated to a remarkable degree on each succeeding conversion. For example, one of the heaviest lines which was converted to trolley-coach operation in late 1940, showed a revenue increase of 12.17 per cent. Periodic checks on each of the lines indicates that the revenue increases have been sustained.

In 17 years there have been 30 lines converted from rail to trackless trolley operation. The routes of these lines range in length from 1.78 to 5.84 miles, and average 3.09 miles. In every case the speed has been increased, these increases ranging from 5.3 to 23.7 per cent. The present trackless trolley system speed, less layover, is 11.21 miles per hour; as rail operation these same lines averaged 9.56 miles per hour. Thus, the average increase in speed has been 17.3 per cent.

The earnings per route-mile range from $26,624 to $109,397, and average $53,541. The earnings per vehicle-mile range from 48.14 to 78.33 cents, with an average of 57.32 cents. It is obvious, from the range of these earnings, that the characteristics of the trackless trolley lines vary considerably. This, of course, is reflected in the amount of service required. Morning-peak headways range from $2^1/_2$ to 12 minutes. Off-peak head-

*This is equivalent to 6.88 per cent return on the investment.

**This is equivalent to 5.30 per cent return on the investment.

ways range from 5 to 15 minutes, and evening-peak headways range from 2 to 10 minutes. The number of passengers carried in the maximum hour varies from a low of 285 to a high of 1,573, with an average per line of 699. This maximum hour occurs in the evening-peak outbound service. The average headway per line during this period is 4.49 minutes, which is equivalent to 13.35 trips per hour per line, thus, each trip averages 52.2 passengers.

The present trackless trolley fleet consists of 330 vehicles, and is made up of 74 40-passenger dual-motor coaches and 256 44-passenger single-motor coaches, with an average age of 5.83 years.

The 30 trackless trolley lines earn at the rate of $5,136,750 annually, operating 8,961,660 miles per year, which is equivalent to 57.32 cents per mile. The operating expenses on these lines range from 42.63 to 57.18 cents per mile, with a weighted average of 45.73 cents per mile. The net earnings are 11.59 cents per mile, or $1,038,656 per year. This is equivalent to an operating ratio of approximately 80 per cent. The breakdown of operating expenses is shown in Table III.

There are in the industry many yard sticks for determining the proper vehicle for a particular line. These yard sticks may include such items as passengers carried in the maximum hour, revenue per route mile, and revenue per vehicle mile. In the last analysis, however, the selection of the vehicle must be based on a thorough study of the particular line and area involved, together with a complete cost analysis covering each type of vehicle.

An example of this technique can be illustrated by the study made on the Hope Street Line prior to its conversion from rail to trackless trolley.

The Hope Street route is 3.02 miles long, extending from the center of Providence, R. I., through a high-grade residential area to the Providence–Pawtucket city line. It required 15 street cars in the evening-peak, operating on a $2\frac{1}{2}$-minute headway. The annual vehicle miles was 332,000 and the annual gross revenue was $184,145 in 1947.

It was determined by preparing a schedule, that 360,000 vehicle miles would be required with either motor bus or trolley coach and that 15 vehicles of either type would be required for service in the evening peak.

The trackless trolley and motor bus analysis worked out as shown in Table II.

It will be noted that a 10 per cent increase in revenue has been assumed for trackless trolley operation and a 5 per cent increase for motor bus operation. This is consistent with the results obtained on other lines.

It has been our policy throughout the entire conversion program to operate motor busses while the overhead was being constructed. The revenue has increased 5 per cent during this period.

A possible point of interest to power companies requested to serve trackless-trolley loads, is the fact that the maximum 15-minute demand-per-vehicle-in-service is 49.1 kw, metered at the generating station high-voltage bus. This peak occurs at about 5:30 p.m. although the maximum passenger load occurs at 5:00 p.m. The power consumption during the winter months equals 5.07 kilowatt-hours per vehicle mile, also measured at the a-c high-voltage bus.

Conclusion

The operating results on the United Electric Railways Company, and other properties throughout the United States, assures the future of the trackless trolley. Our operation has grown from 5 to 330 vehicles in 17 years. This is typical of the growth in the country as a whole. In 1931, there were 163 trolley coaches operated by six companies; today, there are over 6,000 vehicles in service on 42 properties.

The growth of their use on the United Electric Railways Company property is a tribute to the late Colonel Alonzo R. Williams, first vice president and general manager of the company from 1928 until his death in 1948. His steadfast courage and faith in trackless trolleys, in face of considerable early skepticism within the industry, were of immeasurable value in the establishment and growth of our trolley-coach operation, now among the largest in the country.

Table III. Trackless Trolley Operating Expenses in Cents Per Mile for the Year 1947

Operating Expenses	Cents Per Mile
Operating costs	
Garage and trackless trolley operation	
Removal of snow and ice	0.61

No Discussion

Trolley Coaches Replace Busses

A. B. McMILLON
ASSOCIATE AIEE

ECONOMICS have precipitated the substitution of trolley coaches, which are electrically-propelled rubber-tired vehicles taking power from two overhead wires for self-propelled busses on lines of a number of urban-transit properties throughout the country. This affords an opportunity to accurately compare the two vehicles. The results of a number of these bus to trolley-coach changes are recorded here. They constitute significant reading for operators of transit systems and anyone interested in the problems of public transportation.

Need for Comparison

Rapidly rising costs and not-so-rapidly rising fares dictate the use of the most efficient means available for giving transit service. Thus it is particularly important at this time to define the proper range of service density for each type of vehicle at the disposal of our transit systems. Actual case histories are here used to establish the place for trolley coaches. Please note that no claim is made that the trolley coach is the answer to all transit problems. Busses, trolley coaches, modern street cars and rapid-transit equipment all have their place. For example; when modernizing a line with peak headways in the neighborhood of ten minutes or more, busses should be considered, because they have proved to be the most economical vehicle in this service range. When peak headways with large vehicles are less than two minutes the possibilities of the modern PCC (President's Conference Car) car should be investigated, for its economies begin to show up in such heavy service. The trolley coach belongs in the gap between the bus and the PCC car, where peak traffic ranges from 400 passengers per hour upward, or, in other terms, where peak headways are from two to ten minutes. A large majority of the trunk lines in our cities lie in this range.

The comparisons shown in this paper are taken from lines in the 2-to-10 minute headway range where trolley coaches have replaced busses.

Actual Cases

Trolley coaches have replaced busses on lines in Youngstown, Akron, Cleveland, Dallas, Little Rock, Des Moines, and Memphis. There are additional examples, but the substitutions in these cities are typical.

Youngstown, Ohio

Youngstown, Ohio, was first introduced to trolley coaches in 1936 when four motor-bus and two street-car routes were rearranged into four trolley-coach lines. With the new service, peak vehicles required was reduced from 33 to 29, schedule speeds increased 4 per cent and 8.6 per cent peak and base, and vehicle miles for the first three months of operation dropped 11.5 per cent below the same period the previous year. For this same period, passengers carried increased approximately 4 per cent. Youngstown's experience with this change resulted in subsequent conversion of a major part of the system to trolley coaches. In 1947, two-thirds of the total passengers were carried by trolley coaches.

Most of the conversion program in Youngstown was accomplished by forming new trolley-coach lines from combinations of street-car lines and motor-bus lines, but there were lines where the route traveled remained unchanged with the conversion. I have chosen such a motor-bus line for studying the results of trolley-coach substitution for motor busses in Youngstown.

The Mosier-Albert motor-bus line covering 12.20 round trip miles became a trolley-coach line during 1945–1946. Forty-passenger busses served the route before conversion and 44-passenger trolley coaches were substituted. Table I compares operation before and after conversion.

In order to analyze these statistics let us consider Table I item by item. Taking the first entry under Mosier-Albert Line, we see that total annual passengers carried decreased from 5,956,970 to 5,880,476, or 1.28 per cent. For the same period the passengers carried by the entire Youngstown Municipal Railway system fell off from 61,734,576 to 55,043,829, or 10.84 per cent; therefore, the net result is a 9.56 per cent increase in traffic for the Mosier-Albert Line as compared with the whole system. The table shows that annual vehicle miles went from 536,050 miles to 476,946 miles. This is an 11.02 per cent drop in miles over the road for a 1.28 per cent drop in people hauled. The result is a more favorable passengers-per-mile ratio which, according to the table, increased from 11.11 to 12.33. This simply means that each vehicle travels less miles to haul a given number of people, which is better efficiency.

Annual vehicle hours dropped from 51,629 to 49,906 hours. This represents a 3.36 per cent drop in platform expense.

It is interesting to observe that annual revenue for the Mosier-Albert Line went from $281,287.00 in 1944 when busses were running, to $303,528.00 in 1947 after conversion to trolley coaches. A point to note is that there was a 7.9 per cent rise in revenue on this line in the face of a decrease in riders and no raise in fare. This was explained by officials of the company who said that even though system traffic was down and total riders on this line had decreased, the increased revenue on Mosier-Albert was due to the people who did ride putting cash fare in the box

---

Paper 49-105, recommended by the AIEE Land Transportation Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted November 16, 1948; made available for printing December 27, 1948.

A. B. McMillon is Transportation Engineer with the General Electric Company, Erie, Pa.

Table I. Youngstown Operating Statistics for 1944 and 1947

System	1944	1947	Increase or Decrease, Per Cent
Total passengers carried	61,734,576	55,043,829	−10.8
Total passenger revenue	$3,019,470	$2,937,960	− 2.7
Mosier-Albert Line, 9½-minute peak headway	1944 (Bus)	1947 (Trolley Coach)	
Total annual passengers	5,956,970	5,880,476	− 1.3
Total annual vehicle hours	51,639	49,906	− 3.4
Total annual vehicle miles	536,050	476,946	−11.0
Total annual revenue	$281,287.70	$303,528.71	+ 7.9
Total annual operating expenses	$221,281.44	$229,363.33	+ 3.6
Total annual net revenue	$60,006.26	$74,165.38	+23.6
Revenue per mile	52.3¢	63.35¢	+21.1
Passengers per mile	11.11	12.33	+11.0
Revenue per passenger	4.71¢	5.14¢	+ 9.1

instead of buying tokens or weekly passes. The officials stated that these people paid cash because they were largely desire riders (people who did not have to ride public-transit vehicles, but who were attracted by the service). Here we have a definite picture of increased revenue resulting from the attractiveness of the service. It is also noteworthy that Mosier-Albert showed a 7.9 per cent rise in revenue while, for the same period, the system substained a fall in revenue from $3,019,470 to $2,937,960 or 2.7 per cent.

The rest of the comparisons speak for themselves. Net revenue jumped from $60,006 to $74,165 or 23.6 per cent. The revenue per mile went from 52.3 cents to 63.35 cents, a 21.1 per cent increase. Revenue per passenger increased because of more cash fares, as was explained before. Only one other item needs comment, and that is operating expenses. According to the statistics, trolley-coach operating expenses in 1947 show an increase over bus-operating expenses in 1944. This, at first glance, appears unfavorable to the electrically-propelled trolley coach, but the explanation is simple. There were three wage increases between 1944 and 1947 resulting in a labor cost increase of 22.65 per cent. Wages of drivers, mechanics and indirect labor constitute two-thirds of total operating expense. By adding this increase in labor expense only, to motor-bus expenses for 1944, the trolley coach shows a 10 per cent net advantage in operating expense.

Summarizing this example; when electrically-propelled trolley coaches replaced busses, revenue increased, vehicle miles and hours decreased, net revenue increased, passengers per mile increased, and (relative to the system) total passengers carried increased. Also, according to officials of the Youngstown Municipal Railway Company, the Mosier-Albert Line was given a considerably improved service when trolley coaches were installed.

This is not all of the Youngstown story, but the Mosier-Albert conversion is an example of what is being accomplished on this system through extensive use of electric transit. Youngstown hauls approximately 70 per cent of their traffic with trolley coaches.

Dallas, Texas

The first two trolley-coach installations made in Dallas replaced motor busses. The Vickery Line with 11.28 round-trip miles, converted in November 1945, was the first. The Capitol Line with 11.44 round-trip miles followed close behind with trolley coaches beginning operation in February 1946.

Evidence of the success of the Vickery Line conversion came early. Within the first three months of operation with trolley coaches on this line, patronage had increased 10 per cent. The new electric service on the Capitol Line was accepted in like manner by the public.

Table II. Statistics Before and After Trolley-Coach Installation, Dallas, Texas

Total Motor-Coach System Compared with Vickery and Capitol Lines, 4-to-5 Minute Peak Headway

	March to September 1945, Bus	March to September 1946, Trolley Coach	Per Cent Increase
Bus system revenue*	$1,404,776	$1,456,179	3.66
Capitol and Vickery revenue**	$ 220,252	$ 248,759	12.94
Bus system miles*	5,523,946	5,668,262	2.61
Capitol and Vickery miles	712,670	736,481	3.34
Bus system revenue per mile*	25.4¢	25.6¢	.80
Capitol and Vickery revenue per mile	31.0¢	33.8¢	9.00

* Total motor-coach system exclusive of Capitol and Vickery.

** Capitol and Vickery combined because the two routes serve contiguous territories.

The operating results following application of modern electrics on the Capitol and Vickery Lines has resulted in trolley coaches being included in subsequent modernization plans. The Mt. Auburn and Parkview Lines have since been converted to trolley coaches. Others being contemplated are the Harwood, Meadow, and Crosstown Bus Lines.

Table II gives the figures for these first two Dallas lines before and after conversion. These are self-explanatory.

Cleveland, Ohio

The Cleveland Transit System is providing transportation to over a million citizens of Cleveland and the adjacent communities with 284 trolley coaches, 75 PCC cars, 859 street cars, and 709 busses. Upon completion of their presently planned modernization program, however, the total number of rubber-tired electrics in Cleveland will be increased to 629 and trolley coaches will form the backbone of the system.

The first trolley coaches installed were on the Hough Avenue line in 1936. Difficulties during the war years prevented further modernization until 1945. Since then, however, six lines have been converted to trolley coaches. Among them was the Wade Park Line which was a motor-bus line with 11.16 round-trip miles. It was difficult to compare the bus service on Wade Park before the conversion to the new trolley-coach service for various reasons but according to a study made by the Cleveland Transit System preparatory to the Wade Park trolley-coach installation, busses and trolley coaches compared as shown in Table III.

Motor-bus lines included in future plans for trolley-coach conversion are Fulton, Clifton, and Woodland.

Akron, Ohio

The Akron Transportation Company serving nearly 350,000 people in Akron, Barberton, and Cuyahoga Falls, operates approximately 70 trolley coaches on its main trunk lines.

Trolley coaches were first operated in Akron in 1942 when the West Market Street Line, running 5-minute peak headways, was changed from motor-bus operation. The success of these first electrics is indicated by the statement of an official of the transportation company that out of the 32 trolley coaches on the property during the war, 32 were operated every day under the severest service conditions. The only exceptions to this were traffic accident repairs.

Another bus-to-trolley-coach conversion was the Cuyahoga Falls Avenue Line on December 17, 1945. Peak headways were 10 minutes. This line was made a through town route in 1948 and is now called the Bailey-Kenmore-Barberton Line. There is express operation to Cuyahoga Falls on this line during rush hours.

Actual comparative figures as to passengers carried, revenue, and so forth were not available because of a rearranging of the routes accompanying the substitutions, but a schedule speed comparison was obtained on the Cuyahoga Falls Line. The figures show trolley-coach rush-hour schedule speed to be 12 per cent faster than bus. In 1945, before trolley coaches were put in, round-trip time from Main and Exchange to the Bailey Loop was 75-minute rush and 70-minute base for the busses then operating as compared with 67-minute rush and 63-minute base for trolley coach. As a matter of record, the system average trolley-coach schedule speed in Akron for July, 1948, was 11.12 miles per hour including layover.

According to an Akron Transportation Company official, electric transit is the backbone of their system.

MEMPHIS, TENNESSEE

The Memphis Street Railway operates 204 rubber-tired electrics over 147 round-trip miles of route and there are more to come. The most recent change from bus to trolley coach was the Crosstown extension, a 7-mile round-trip run with peak headways from 4 to 5 minutes.

The next bus to trolley-coach conversion will be the Jackson Feeder Bus Line covering 4.0 round-trip miles. Following this will be the conversion of the Faxon Line covering 9.0 round-trip miles, running 3- to 4-minute peak headways. This expanded service will require a total of 18 additional coaches. The overhead line is now under construction.

Table III. Vehicle Comparison, Cleveland, Ohio

Wade Park Line Study, 2-to-3 Minute Peak Headways

	40 Passenger Gasoline Bus	40 Passenger Trolley Coach
Vehicles required	32	26
Annual rides	7,997,793	7,997,793
Annual miles	820,352	774,642
Annual hours	91,568	80,038
Annual expenses	$287,136.61	$244,176.32

Table IV. Statistics Before and After Trolley-Coach Installation, Des Moines, Iowa

Installed on Second Avenue Line, May 16, 1948, 6-Minute Peak Headways

Type Data	1947 June–July, Bus	1948 June–July, Trolley Coach	Increase or Decrease, Per Cent
System revenue	$543,399	$577,590	+ 6.3
Second Avenue Line revenue	14,623	18,083	+23.6
System miles	$1,438,195	$1,287,170	−10.5
Second Avenue line miles	48,519	45,552	− 6.5
System revenue per mile	37.8¢	44.9¢	+18.8
Second Avenue revenue per mile	30.1¢	39.6¢	+31.6

DES MOINES, IOWA

In Des Moines, trolley coaches are called "curbliners." The complete system includes ten curbliner routes, six street-car routes and eight motor-bus routes. The latest curbliner route was installed May 16, 1948. This was the Second Avenue Line which was served previously by motor busses. Comparing revenue for June and July 1947, before conversion, with the same period in 1948 shows a 23.6 per cent increase. System revenue showed a 6.3 per cent increase for the same period. Total miles operated on the Second Avenue Line in June and July 1948 as compared with the same period in 1947 showed a 6.5 per cent decrease.

The total result, considering the 23.6 per cent increase in revenue and the 6.5 per cent decrease in miles traveled indicates that in Des Moines more passengers are carried more efficiently with modern electric curbliners.

Additional proof of the quality of service rendered by trolley coaches in Des Moines lies in the statement by the Des Moines Railway Company that they operated every one of their 132 trolley coaches every day of every week for four years during the war, with the exception of vehicles with body damage caused by collisions.

LITTLE ROCK, ARKANSAS

The Capital Transportation Company has launched a modernization program which began December 26, 1947. At present, new electric passenger equipment on the property consists of 35 trolley coaches operated on what was formerly four lines. Of these four lines, two were converted from bus operation. They are the South Main, and West Ninth Street Lines. South Main is now combined with Pulaski Heights to make one route. West Ninth is combined with the Fair Park Line. These lines run 5-minute peak headways.

According to the company, future plans for trolley-coach installations include at least two other motor-bus lines.

Analysis of Cases

The facts and figures recorded in all of the foregoing examples compare the bus and trolley coach on two points as related to service on trunk lines in the 2-to-10 minute peak-headway range. These points are:

1. Ability to attract riders.
2. Operating economy.

The figures show the trolley coach to be superior on both points.

These points, which can be substantiated by an analysis of the actual cases, could stand further study. For example, why does the trolley coach serve a given line more economically than a bus?

Figure 1. Modern trolley coach

Economies offered by the trolley coach lie in:

1. Savings resulting from the smaller requirements as to quantity of vehicles and number of vehicle hours and miles.
2. Electric equipment maintenance being less expensive than engine and transmission maintenance.
3. Trolley-coach body and chassis maintenance being less expensive than bus maintenance because of smoother operating equipment on trolley coaches.
4. Electrical energy being more economical than petroleum fuels.
5. Brake maintenance advantage of the trolley coach due to electrical braking.
6. Tire and tube mileage advantage of the trolley coach due to less heat generated at the brake drums.

These factors generally add up to an expense comparison such as is shown by Table V.

The figures in Table V are further enhanced by the fact that trolley coaches will operate less miles and hours than busses in performing a particular service.

There are various reasons why trolley coaches are able to attract more revenue than busses. Important among them are the following:

1. Wide spacious aisles allowing more freedom of movement.
2. No engine roars, and a minimum of brake squeals.
3. Fast and comfortable.
4. Clean, well lighted, well ventilated, and devoid of the odor of engine exhaust gases.

Summary

This paper cites certain cases where trolley coaches replaced busses as indicative of a trend. Then the results of the replacements are recorded to explain the trend and the significance of sound vehicle selection.

For the most part, the routes chosen for this paper traversed the same streets before and after conversion. This type of route is necessary for accurate comparison of all the factors involved. Where the line in question changed, no attempt was made to compare figures which would be affected by the change. For example, if half of a line served a different area after conversion, no attempt was made to compare total revenue, passengers carried, or vehicle miles before and after conversion.

Table V. Typical Operating Costs

	Year	Trolley Coach	Bus
Boston, per vehicle mile	1946	36.7¢	43.5¢
San Francisco, per vehicle hour	1947	$3.39	$4.16

If detailed figures were not available, the conversion was merely cited, possibly with statements from the company, without making inferences or drawing any unfounded conclusions.

Conclusion

These actual case histories are good examples of how trolley coaches can improve gasoline-bus operation on a heavy-service line. The better operation which resulted in every case is indicative of the advantages of the trolley coach over self-propelled vehicles on trunk lines. More capacity, higher schedule-speed ability, less expensive maintenance and more attractive service enable this modern rubber-tired electric vehicle to give better service to the rider and greater economy to the operator. Thus the trolley coach confirms the fact that modern electric-transit equipment has a large field of application in our cities.

Confirmation also lies in the fact that almost every transit system cited here has plans for future bus to trolley-coach conversions. There are also companies whose experiences were not included here who have such conversions in their modernization plans. For example, the New Orleans Public Service, Inc., in New Orleans, La., plans to convert the City Park Line from the present bus operation to trolley coaches. Their modernization program at present calls for 169 trolley coaches.

To satisfy the mounting urgency for more efficient operation, we can expect the modern trolley coach to be applied at an increasing rate on heavy-service lines requiring peak headways of from two to ten minutes.

No Discussion

Application of Experimental Test Procedures and Methods of Analysis of Results to Research Problems in Magnetic Recording

C. S. THOMPSON
NONMEMBER AIEE

Synopsis: This paper discusses an investigation designed to determine, as functions of bias- and signal-current values and of recording media and recording and playback heads, the response characteristics of a magnetic recording system. The theoretical background presented permits the prediction of frequency response curves in terms of relative values. These curves are obtained from data determined by measurements, calculations, and experiments on the component parts of a magnetic recording system. Subsequent to the theoretical material there is a description of a systematic method for planning experimental procedure, plotting the results, and presenting the test data for a magnetic recording system. Other data displayed here proves the superiority of thin laminations (0.002 inch thick) over thick laminations (0.005 inch thick) as core material for the heads of a magnetic recording system.

MAGNETIC recording is a system for impressing time variations in magnetic field strength upon a ferromagnetic material, usually in the form of a fine wire or a thin film superimposed on a paper or plastic tape. The recording is accomplished as the tape or wire moves at a constant speed through the recording apparatus. Magnetic recordings also have been made on rotating disks or cylinders, but these are not a concern of this paper.

The variations in magnetic field strength to be recorded exist at the pole tips, in the boundary of an air gap in the core of an electromagnet. The magnetic field at the pole tips is produced by a current in the coils of the electromagnet. The electromagnet is referred to as the recording head. Variations of current strength in the recording head cause proportional variations in magnetic field strength to be recorded on the wire or tape. The most common use of magnetic recording is to record speech or music. Acoustic impulses may be translated into recording-head current variations by any conventional method.

Advantage is taken of the remanence of the magnetic recording medium to retain the effect of the magnetic field intensity existing in the air gap of the recording head at the instant in which any particular portion of the recording medium travels across the air gap.

Remanence is defined, according to the American Society for Testing Materials, as "the magnetic induction which remains in the magnetic circuit after the removal of the applied magnetic force. If there is an air gap in the magnetic circuit, the remanence will be less than the residual induction."

Residual induction is defined as "The magnetic induction corresponding to zero magnetizing force in a magnetic material which is in the symmetrically cyclically-magnetized condition." The difference between remanence and residual induction is caused by the demagnetization effect discussed later. Where remanence and residual induction are used in this paper, they are used in the sense of the preceding definitions.

Figure 1 (A) shows the signal to be recorded, as a sine wave of current in the coils of the recording head; Figure 1 (B) shows an enlarged view of the recording wire or tape. The small arrows represent symbolically the alignment of the so-called "molecular magnets." Immediately below the wire or tape, the recording head is shown with flux lines threading its core. The bottom leg of the core is surrounded by an energizing coil. The pole tips are marked with an assumed polarity indicated by the symbols *N* and *S*.

The recording medium enters the recording head, previous to time t_1, in the unmagnetized condition indicated by the heterogeneous state of the molecular magnets. At time t_1, the current starts to build up from zero. As the current increases in strength, more and more molecular magnets are aligned until, at time t_2, when the current has reached maximum value, the maximum number of magnets have been aligned and the maximum magnetic intensity along the wire is produced. Decreasing current produces less and less magnetic field strength at the pole tips, resulting in a decrease in magnetic intensity along the wire until, at time t_3, the intensity is reduced to zero. Increasing the current in the opposite sense repeats the process of aligning the molecular magnets in proportion to the current strength, but in the opposite direction.

As the recording medium moves along, the molecular magnets are removed from the magnetizing field. Thus the medium retains the magnetic intensity indicated by the remanence value. Notice that free magnetic poles are formed at the approximate times t_1 and t_3 and are indicated on the wire by the polar symbols *N* and *S*. The distance between these

poles indicates the approximate effective length of what will be referred to as the "fixed magnets" existing in the recording medium as a result of the recording process.

If a sample of the recording medium in ring or closed magnetic circuit form be measured by a B–H loop tracer, the residual induction will be that value of B, referred to as B_r, which corresponds to zero value of H. The fixed magnets in the recording medium, not being in a closed magnetic circuit when removed from the recording head, will exhibit a lower value of B, referred to as B_d, the remanence value. The maximum value of H at the tip of the hysteresis loop is the same in both the open and closed magnetic circuits. The reduction in B from B_r to B_d results from the demagnetization effect of the air-gap path of the return flux from the N pole to the S pole outside the recording medium.

The demagnetization effect, a function of the ratio of the thickness of the fixed magnets to their effective length, becomes greater as the ratio becomes greater. For a bar magnet with a length 100 times greater than its thickness, the demagnetization effect is negligible, and B_d may be taken equal to B_r.

Obviously, if a constant wire speed is assumed, the effective magnet length becomes shorter as the frequency of the recorded signal becomes higher. For very high frequencies the effective magnet length may approach, or become less than, the wire diameter. In such cases the demagnetizing effect is very powerful, resulting in a large attenuation of the value of magnetic intensity in the recording medium at high frequencies. This demagnetizing effect is one of the important sources of distortion in a magnetic recording system.

Another source of distortion is the nonlinear relation between B and H. This nonlinearity is severe, as can be seen by observing the familiar hysteresis loop.

Early investigators of magnetic recording were unable to overcome the serious distortion of the hysteresis loop (Figure 5) until it was discovered that, if the audio, or lower frequency, signal was mixed with a much higher frequency current and both recorded at their proper amplitudes, so far as the recorded signal was concerned, a linear relation between B and H was approached. The high-frequency current is referred to as the "bias current." Assuming an upper response curve cutoff frequency of 10 kc beyond which high-frequency components are sharply attenuated, and if the bias frequency is 30 kc or higher, no bias frequency component will be observed in the response of the recording system. The use of a biasing current does not make the relation between B and H completely linear, so that slight distortions due to nonlinearity still remain. D-c biasing has been used with only mediocre results.

Several detailed explanations of the action of high-frequency biasing currents have been published. Some of the explanations are at variance with each other as to the manner in which the biasing current acts to make the relation between B and H more nearly linear. While it is felt that the action of the bias current should be the subject of a more rigorous mathematical analysis, an article by Lynn C. Holmes and Donald L. Clark offers a well-thought-out theory.[1]

Figure 1(B) shows that, as the recording medium moves, it crosses the pole tips of the play-back head. Part of the flux surrounding the fixed magnet passing across the play-back head, threads through the core of the play-back head. The amplitude of the flux density thus set up in the play-back head, is proportional to the magnetic intensity existing in that part of the recording medium passing across the air gap. The directional sense of the flux is determined by a polarity of the fixed magnet. The building-up and dying-down of the flux in the core causes an electromotive force to appear at the terminals of the coil wound around the lower leg of the core of the play-back head. Again, this electromotive force is proportional to the magnetic intensity existing in the recording medium at the moment the medium passes across the air gap of the play-back head. The play-back signal produced by this passage is shown in Figure 1(C). The 90-degree shift in phase between the sine wave of magnetic intensity and the sine wave of electromotive force produced

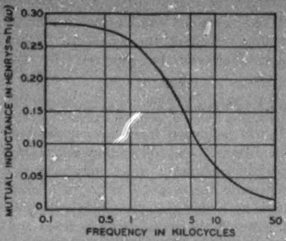

Figure 5. Mutual inductance of recording and play-back heads versus frequency

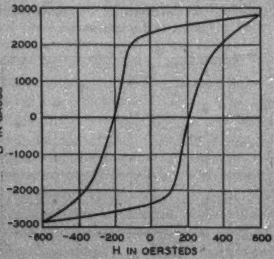
at the terminals of the play-back coil, is of mere academic interest.

The amplitude of the play-back electromotive force is at a rather low level, and must be amplified considerably before being used in a measuring instrument or loud-speaker.

In addition to the distortions produced by the demagnetization effect and the nonlinear relation between B and H, other magnetic, electrical and mechanical characteristics add to the distortion which may be produced in the magnetic recorder. The Bartol Research Foundation of The Franklin Institute, under contract to Special Devices Center, United States Navy, developed a theoretical background for the analysis of the factors influencing the response of a magnetic recorder. A summary of the analysis is presented here as the basis for the work covered by this paper.

Using data determined by measurements, calculations, and experiments, a concrete example of a frequency response curve, predicted from the known characteristics of each of the component parts of a magnetic recording system, has been worked out. It is not possible to obtain absolute values for the response curve, because some of the magnetic and electric loss factors can not be isolated experimentally, and because an exact mathematical solution to some of the problems is far too complex. Consequently, the theoretical work can provide a solution only in terms of relative values. This is a minor difficulty, however, since the value of the theoretical treatment lies in its ability to provide the tools for estimating the relative effects of suggested improvements, and to reveal the need for, and the nature of, improvements.

Figure 6. B versus H for recording-wire sample



Mathematical Background

Assuming it is possible to evaluate the terms involved, the frequency response characteristics for the recording head, the play-back head, and the recording media (wire or tape) of a given magnetic recording system may be calculated from the following transfer equation established by Shutt

$$\frac{e_0}{e_i}=\frac{N_1N_2Z_0'(\omega)\omega h_1(\omega)m(\omega,v)h_2(\omega)}{[Z_i(\omega)+j\omega L_1(\omega)+R_1(\omega)][Z_0(\omega)+j\omega L_2(\omega)+R_2(\omega)]} \quad (1)$$

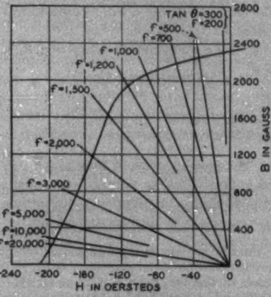


Figure 7. Second quadrant B–H curve

This formula is developed logically from the behavior of the elements of the magnetic recording system. It was presented by Ralph Shutt in an unpublished report to the Special Devices Section, United States Navy. ("Some Theoretical Considerations Concerning Magnetic Sound Recording," Bartol Research Foundation of the Franklin Institute, Swarthmore, Pa., October 22, 1946.)

The elements of the preceding equation are displayed functionally in Figure 2. Each box, corresponding to a functional element, contains the symbols describing its behavior as a function of signal frequency and the speed of the recording medium moving past the recording head and play-back head. The electric circuit elements involved are shown in Figure 3 for the input circuit, and in Figure 4 for the play-back circuit.

The symbols used in the diagrams and in the preceding equation are given in the list of symbols at the end of this paper.

THE FUNCTION, $h_1(\omega)$

The magnetic field in the pole tips of the recording head, available for magnetizing the wire or tape, is a function of the magnetic skin effect in the magnetic circuit of the recording head. The magnetic skin effect is represented by the function $h_1(\omega)$ for a given lamination thickness. Decreasing the lamination thickness reduces the magnitude of the magnetic skin effect. It can be shown that

$$h_1(\omega)\sim M_1(\omega) \quad (2)$$

where M_1 (ω) is the mutual inductance between the main coil of the recording head and an exploring coil wound on a pole tip. $M_1(\omega)$, obtained by means of an impedance bridge, is plotted against frequency in Figure 5. Since h_1 (ω) is proportional to M_1 (ω), and since absolute values are not concerned immediately, assume that

$$h_1(\omega)=M_1(\omega) \quad (3)$$

and substitute accordingly where h_1 (ω) appears.

THE FUNCTION, m (ω,v)

The symbol m (ω,v) represents the demagnetization effect existing in the wire or tape as it comes under the influence of the applied magnetic field in the gap of the recording head.

B–H curves are derived from samples having a large ratio of length to diameter; usually well above 50 to 1. This ratio, or a larger one, is used for the express purpose of obtaining a B–H curve under conditions free from any appreciable influence of the demagnetization effect. It is possible to predict the extent to which the remanence value would be lowered by the demagnetization in case a sample, measured under conditions of a large ratio of length to diameter, is to be used in a situation in which the ratio of length to diameter is small (less than 100 to 1). This prediction may be made, using methods devised to determine the magnitude of the demagnetization effect, by applying a correction factor to the standard B–H curve. The correction factor is calculated (in our case with the aid of predetermined graphs calculated by Shutt) from a knowledge of the ratio between the effective length and the thickness of the individual magnets appearing

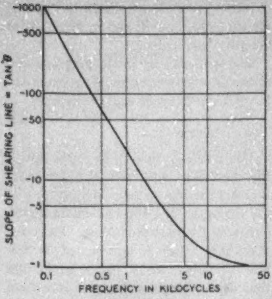

Figure 8. Slope of shearing line = tan θ versus frequency

Wire diameter = 0.004 inch
Wire speed = 5 feet per second

in the wire or tape during the recording process.

Figure 6 is submitted as the *B–H* curve of a representative sample of recording wire.

For our purpose, we are interested only in the second quadrant of the *B–H* curve. An enlarged view of the second quadrant is given in Figure 7.

Typical values of the magnitude of the demagnetization-effect correction factor are given by the curve in Figure 8, which shows the relation between the frequency and the slope of a shearing line. The slope of the shearing line is applied as a correction factor to the second quadrant of the *B–H* curve in Figure 7. Figure 8 is based on calculations by Shutt for the special case of 0.004 inch diameter wire moving at 5 feet per second.

The negative tangent of the angle θ, (slope of the shearing line) = the demagnetization factor if the B and H coordinates are drawn to the same scale. Since these co-ordinates are not drawn to the same scale in Figure 7, the actual slope of the shearing line is determined by applying the proper scale factor.

The slope of the shearing line is plotted against frequency for 0.004 inch diameter wire. One shearing line for each frequency is drawn on the curve in Figure 7. These lines are drawn radially from the origin, with the proper slope dictated by the frequency given in Figure 8. The intersections of the shearing lines and the *B–H* curve indicate B_d, the corrected values of B_r which correspond to the frequency under consideration, and which represent the relative value of the result of the demagnetization effect.

Figure 9 shows the plot of B_d, remanent magnetism, against frequency. For the purpose of this paper the function $m(\omega,v)$ is taken to be equal to the corrected B_r as a function of frequency, and, consequently the corrected B_r is the term used in the equation.

THE FUNCTION, h_2 (ω)

h_2 (ω) is a factor which decreases with frequency and may be shown to be composed of two parts

$$h_2(\omega) = h_2'(\omega) \times h_2''(\omega) \tag{4}$$

h_2' (ω) is quite similar to h_1 (ω) in that it is directly proportional to the mutual inductance between the main coil of the play-back head and an exploring coil wound on the pole tips. Since the functions h_1 (ω) and h_2' (ω) are similar, and the recording and pick-up heads may be almost identical (in some cases the same head is used both for recording and play-back), the curve of Figure 5 will be used to represent h_2' (ω) as well as h_1 (ω).

h_2'' (ω) is equivalent to a function, $h_3 \times \frac{(2\pi)}{\lambda}$ developed by Shutt where

λ = wave length of recorded signal
= 2 (effective magnet length)

The following concept may prove useful in describing the physical phenomena responsible for the frequency discrimination expressed by the function h_2'' (ω)

Fluctuating magnetic potentials are set up at the pole tips of the play-back head, as a result of the varying amounts of magnetization which were fixed in the wire or tape as it passed through the recording head. The effective permanent magnets found in the wire have a length inversely proportional to the signal frequency impressed at the recording head. When the effective length of these magnets approaches the dimension of the gap width in the play-back head, the geometrical distribution of the flux within the air gap, and consequently at the pole tips, becomes a function of the magnet length. For linear reproduction the flux in the pole tips should be proportional only to the intensity of magnetization. The departure from linearity resulting from changing geometrical flux distribution, caused by varying magnet length, is expressed by the function $h_2''(\omega)$, shown graphically by the curve of Figure 10. Negative values of $h_2''(\omega)$ indicate a reversal of phase of the play-back signal.

THE QUANTITY, ω

Assuming a constant rms value of alternating sine-wave flux, the output voltage of a transformer or other inductor is proportional to $d\phi/dt$ and, consequently, to the frequency, f. Therefore the output voltage of the play-back head is proportional to the signal frequency, as well as to the other factors mentioned in this summary.

The combined effect upon the output voltage of all of the significant factors mentioned can be expressed by the product

$$\omega \times h_1(\omega) \times m(\omega,v) \times h_2'(\omega) \times h_2'(\omega) \sim e_0 \tag{5}$$

It will be shown later that, under test conditions, the above product is the only part of equation 1 which influences significantly the response curve of a magnetic recording system. Calculating this product for the frequencies concerned, and plotting the results against frequency, one obtains the theoretical fidelity response curve of a magnetic recorder under conditions in which the current input to the recording head is constant. The resulting plot for this product, as developed from the functions outlined in this summary, is shown in Figure 11. Negative values of output indicate a reversal of phase of the output signal.

The response curve obtained under the foregoing outline is valid under the following conditions and assumptions:

1. The magnetizing current

$$i_1 = \frac{e_t}{Z_t(\omega) + j\omega L_1(\omega) + R_1(\omega)} \tag{6}$$

has been kept constant. This is one of the conditions of the experiment.

2. If the impedance Z_0 (ω) of the amplifier following the play-back head is large compared to the impedance $[j\omega L_2(\omega) + R_2(\omega)]$ of the play-back coil and if

$$Z_0'(\omega) = Z_0(\omega) \tag{7}$$

then

$$\frac{Z_0'(\omega)}{Z_0(\omega) + j\omega L_2(\omega) + R_2(\omega)} \approx 1 \tag{8}$$

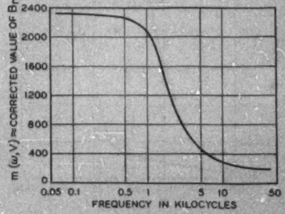
Rewriting equation 1

$$e_0 = \frac{e i N_1 N_2 Z_0'(\omega) \omega h_1(\omega) m(\omega,v) h_2(\omega)}{[Z_t(\omega) + j\omega L_1(\omega) + R_1(\omega)][Z_0(\omega) + j\omega L_2(\omega) + R_2(\omega)]} \tag{9}$$

and observing that

$$i_1 = \frac{e_t}{Z_t(\omega) + j\omega L_1(\omega) + R_1(\omega)} = \text{Constant} \tag{10}$$

Figure 9. *Br* corrected for demagnetization effect versus frequency



$$N_1N_2 = \text{Constant} \tag{11}$$

$$\frac{Z_0'(\omega)}{Z_0(\omega)+j\omega L_2(\omega)+R_2(\omega)} \approx 1 = \text{Constant} \tag{12}$$

Equations 10, 11, and 12 contribute nothing toward a study of the variations of e_0 with respect to frequency. This leaves for consideration only

$$e_0 \sim \omega h_1(\omega) \times m(\omega,v) \times h_2(\omega) \tag{13}$$

which is again proportional to

$$f \times h_1(\omega) \times m(\omega,v) \times h_2'(\omega) \times h_2''(\omega) \times h_2''(\omega) \tag{14}$$

which will be considered equal to e_0. e_0 is the output voltage, plotted against frequency in Figure 11. Equation 1 can be used to show what will happen when the input, e_1, varies; particularly what can be done when e_1 is controlled (pre-equalization). Equalization may also be accomplished by establishing and controlling the inequality, $Z_0'(\omega) \neq Z_0(\omega)$, as a function of frequency (post equalization). See equation 7.

Development of Test and Analysis Methods

For the most part, the tests performed to date had for their purpose a determination of the influence exerted by component-part characteristics upon the over-all response. By altering a characteristic of the component part under tests, and by investigating again the over-all response, the influence of component-part characteristics upon over-all fidelity could be determined. One of the important objectives of the tests conducted at The Franklin Institute was the correlation of over-all fidelity with the influence of the various functions included in equation 5.

The nature of the project was such that the main interest lay in the effect of lamination thickness and of the *B–H* characteristics of the recording media, on the fidelity of reproduction.

The majority of the tests made on the magnetic recording system were in the form of sine-wave recordings, at various amplitudes and frequencies of the signal and bias currents. Experimental performance was judged from the results shown by fidelity curves drawn from the frequency versus response data obtained at the play-back head. Because of the nature of the project, it was considered desirable to measure the harmonics as well as the fundamental appearing at the output terminal of the play-back head.

Frequency versus response data was obtained with a General Radio Wave Analyzer. While response tests using an intermodulation measuring instrument may be conducted with profit, intermodulation testing does not estimate the harmonic content with ease, and, since an interest in harmonic content existed for special reasons, the majority of tests conducted up to the present time have been made with the conventional wave analyzer. It is planned that intermodulation tests will be conducted in the future as an aid to estimating the performance of magnetic systems used in recording speech and music.

Considering the complexity of the simultaneous action of bias and signal currents upon the nonlinear transfer characteristics of the loop, it is obvious that, in order to arrive at correct values of bias and signal currents, considerable experimenting must be done. It may be said that "optimum" values are desired. Optimum values may be defined as those values of bias current and of signal current which give maximum output, if these values are consistent with the requirement that the nominal operating range of signal current variation will be in the most linear portion of the signal (input versus output) saturation curve, that is, somewhere below the knee of the curve. This definition implies that operating in a part of the output curve which approaches linearity minimizes harmonic distortion.

An attempt to obtain optimum conditions discloses that the optimum bias current depends on the signal current chosen, and that the optimum signal current depends on the bias current chosen. The optimum bias current and the permissible range of signal current variation are quite interdependent.

Prevalent methods for adjusting the values of bias and signal currents consist of observing the effects on the output of varying the values of either the bias or the signal current, by means of an oscillograph which shows the received wave form, by using an intermodulation instrument or output meter, or by any other output-measuring device. Bias current adjustment is alternated with signal cur-

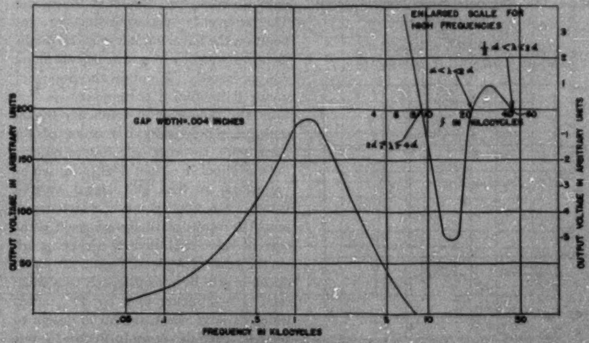
Voltage at play-back coil versus frequency at constant recording circuit



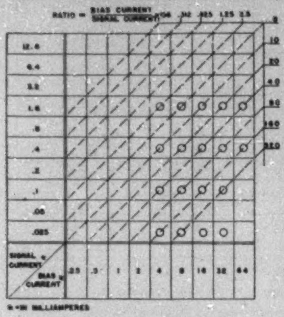


Figure 12. Test schedule sheet

rent adjustment until the operator judges that suitable operating values have been achieved. Most of the methods described in the literature seem to be based on similar cut-and-try procedure.

Considering the importance of determining correctly the proper operating values of bias and signal currents for a given magnetic recorder design, it seemed expedient to establish a suitable method for such a determination. The most reasonable procedure for this test was to obtain fidelity characteristics throughout a suitable range of both bias and signal currents, plot the results, and then determine from the plotted results which bias current could be considered "optimum" from the point of view of signal-current range and fidelity requirements. The information presented by the resulting graphs was complete, concise, and final.

A systematic plan for choosing a range of bias and signal currents was achieved. This plan involved choosing particular values of test currents at equal intervals on a logarithmic scale. The fundamental intervals chosen were such that each increasing value was double the previous value. In case these steps were too coarse, the fundamental intervals were halved according to the logarithmic scale.

Figure 12 shows a test schedule in which the fundamental values of signal currents are shown in the left hand column. The bottom row shows the fundamental values of bias currents.

In planning a test, reasonable and systematic combinations of bias- and signal-current values are chosen. For each of the chosen combinations, the frequency response curves are obtained. The selected combinations of bias and signal currents are indicated by placing a small circle at the intersection of the rows and columns of the test schedule sheet corresponding to the desired values of signals and bias currents. If the intervals between the fundamental current values shown on Figure 12 are too large, auxiliary sheets with half intervals may be prepared.

In order to analyze logically the characteristics of such component parts of a magnetic recording system as recording head, play-back head, and recording media, it has been found highly desirable and informative to obtain frequency response curves at each of a reasonable number of well-chosen combinations of bias and signal currents.

Some of the ways in which the frequency response data may be analyzed and presented will be described. Figure 13 shows a frequency response curve as obtained with the wave analyzer. These curves show the output of the fundamental frequency, together with the accompanying harmonic content, as functions of signal frequency. Each curve of harmonic content is labeled with a number representing the multiple of the fundamental frequency for that harmonic. The frequency corresponding to any point on the harmonic curve is the fundamental frequency at which the harmonic was measured. To obtain the frequency of the harmonic, it is necessary to multiply the fundamental frequency by the multiple representing the order of the harmonic. In order to estimate quickly the variations in output fidelity caused by variations in bias and signal current values, each fidelity curve, which represents the results of a test performed at the current value indicated by a check mark on the test schedule of Figure 12, is reduced in size by a pantograph to a small card, 1 $^{11}/_{16}$ inches long by $1^1/_4$ inches wide. A large sheet, similar in design to the test schedule shown in Figure 12, but with each square $1^{11}/_{16}$ inches long by $1^1/_4$ inches wide, is prepared. The rows and columns of this larger sheet, called the Test-result Schedule Sheet, designate bias and signal current values. The small cards, each containing a reduced fidelity curve, are affixed to the large sheet, in the appropriate space corresponding to the intersection of the row and column showing the value of the bias and signal current at which the fidelity curve was obtained.

Each card is ruled to a log–log scale. The left-hand edge of each card corresponds to the ordinate at 100 cycles per second, the second vertical line, to 1 kc; the third line, to 10 kc; and the right hand edge, to 100 kc. The bottom edge corresponds to an output level of 0.01 millivolt; the second horizontal line, to 0.1 millivolt; the third line, to 1 millivolt; the fourth line, to 10 millivolts; and the top edge, to 100 millivolts. It was preferred to plot the output in absolute values on a logarithmic scale, rather than in decibels on a linear scale.

The small cards show the fundamental as a heavy solid line, the second harmonic as a fine solid line, and the third harmonic as a dotted line.

Figure 14 shows a test-result schedule sheet which displays the variation of fidelity characteristics throughout a range of bias and signal current values. This test provided data on the fidelity characteristics of a magnetic recording system employing the commercially produced recording wire, designated as wire *A*. A similar test employing a commercial recording wire, designated as wire *B*, was performed with the results shown in Figure 15. Aside from a slight difference in the choice of the range of test values for bias and signal current and the difference in recording media, the test conditions and circuit elements of the entire recording system for the two investigations were identical.

The test results given by Figure 13 were not obtained from the investigations conducted on either wire *A* or wire *B*, and, consequently, are not to be found in the curves of either Figures 14 or 15.

The preceding *qualitative* method of presenting large amounts of data in a small space permits all variations in performance to be observed at a glance.

To provide a presentation of *quantitative* data in a concentrated form, additional graphs were prepared from data furnished by the original frequency response curves, the reduction of which is shown qualitatively by the Test-result Schedule Sheet. In order to make the best of the information obtained in the

Figure 13. Response curves, output versus frequency

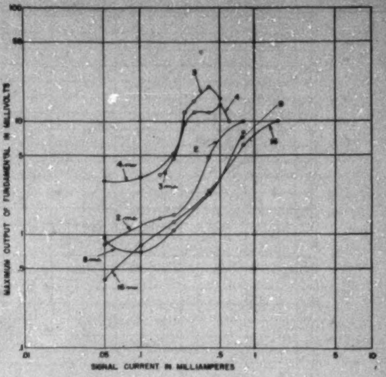

Figure 17 (right). Wire *B*—Maximum output of fundamental versus signal current at constant bias currents

basic curves, a number, representing magnitude or value, was assigned to an outstanding characteristic of the data presented by each curve sheet. Since each curve sheet represents data taken at a particular value of bias and signal currents, the "assigned value" corresponds to only one value of signal and bias current. Thus, the assigned value may be plotted against the variation of signal currents with the bias current held constant, or vice versa. Each assigned value should be regarded as a summation of all the data presented by one curve of output voltage versus frequency. Though this report treats bias and signal currents as adjustable factors, under actual operating conditions the bias current is held constant, while signal-current amplitude and frequency vary widely.

In preparing Figure 16, the maximum voltage output with wire *A*, was considered the significant data on which assigned values should be based. Consequently, Figure 16 shows assigned values at specific signal and bias currents. The extent to which the maximum output voltage varies with signal current is plotted for various values of bias currents. Figure 17 shows a similar plot for wire *B*.

Because the harmonics generated in magnetic recording are unwanted frequencies, and because the fundamental is the frequency in which we are interested, it is desirable to express the level of harmonic content in some definite relation to the amplitude of the fundamental. This may be done easily at any given frequency. However, it would be very convenient if a method could be contrived to express, by means of one number or assigned value, an over-all level of harmonic content with respect to the output level of the highest-amplitude harmonic in relation to the fundamental. This number or assigned value should attempt to express the difference in level between the highest-amplitude harmonic and the fundamental frequency throughout a wide range of the frequency covered by one frequency response curve. Assuming that what is needed is a number to express the average distance between the fundamental output level and the harmonic output level, the method chosen measures the area between the fundamental and the highest harmonic level. The area measurement is limited in all cases to the area lying between the vertical lines given by the 300 and 10,000 cycles per second points, and between the curves giving the output levels of the fundamental and the highest amplitude harmonic. This area was measured with a planimeter.

Since the area was measured on logarithmic paper in terms of linear dimensions (length squared), the area probably has no physical significance. However, from an arbitrary point of view, the area does express a relation to the average difference in level between the fundamental and its highest-amplitude harmonics in decibels, or in a similar logarithmic unit. This method affords a useful estimate of the average separation between the fundamental and the nearest harmonic.

The method of area measurement was used to compare the performance of wire *A* and with wire *B* with respect to harmonic content. Figure 18 shows a family of curves expressing the relation between signal current and area between fundamental and harmonic for wire *A*. Each curve is obtained at the constant value of bias current indicated on the curve. Figure 19 presents a similar graph for wire *B*.

The laboratory results, shown by the frequency response curve of Figures 14 and 15 and the quantitative-analysis curve of Figures 16 to 19 inclusive, were presented more for the purpose of demonstrating a logical system of analysis than for showing the results of any particular test. However, inspection of the curves of Figures 16 and 17 shows that, for a given signal current, the maximum output obtained from wire *B* is greater than that obtained from wire *A*. From the point of view of securing maximum output, the bias current for wire *A* should be eight milliamperes, and for wire *B*, three or four milliamperes.

Harmonic distortion is very nearly the same for both wires *A* and *B*. Minimum distortion is obtained for wire *A* by using a bias current of eight milliamperes, while the minimum distortion for wire *B* is obtained by using a bias current of four milliamperes. Thus, for maximum output with minimum distortion, a bias current of eight milliamperes should be chosen for wire *A* and four milliamperes for wire *B*.

Test for Thin-Lamination Head

The first phase of a significant investigation concerning the question of proper core lamination thickness for magnetic recording and play-back heads has been completed. Studies by Shutt indicated that considerable improvement in high-frequency response could be gained by using laminations thinner than those ordinarily employed in past commercial design and development work. The

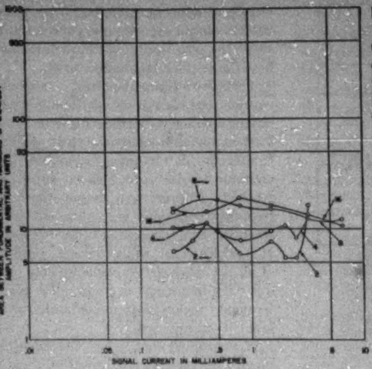

Figure 18 (left). Wire *A*—Area between fundamental and harmonic of greatest amplitude versus signal current at constant bias currents

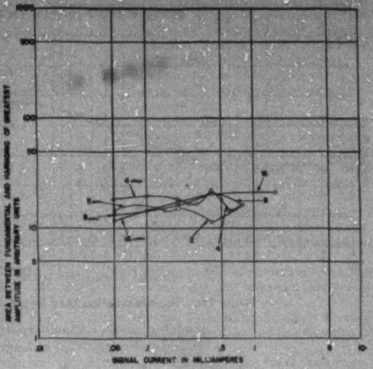
Figure 19 (right). Wire *B*—Area between fundamental and harmonic of greatest amplitude versus signal current at constant bias currents



usual practice is to employ laminations of a thickness ranging from 0.005 inch to 0.015 inch. It was believed that laminations thinner than 0.005 inch would show a decided improvement in the high-frequency region. Accordingly, a play-back head having laminations of 0.002 inch in its core structure was built and tested.

Figure 20 shows a block diagram of the apparatus and instruments used in obtaining the frequency response characteristics for both the wire-comparison test and the thin-lamination test.

In order to obtain a direct comparison between the performances of thick and thin laminations, an experimental procedure was adopted which permitted frequency response curves to be obtained, under identical recording conditions, from a thick-lamination head, 0.005 inch thick, and a thin-lamination head, 0.002 inch thick, each in the play-back position. Both of these heads were of similar geometric design. The response curves in this test were obtained with an automatic sound-level recorder, rather than with the wave analyzer.

The advantage sought in using thin laminations is a greater fidelity than has been possible previously, in the high-frequency region. Thick laminations in the recording head result in high-frequency attenuation of the signals impressed upon the recording medium. Thick laminations in the play-back head result in a further attenuation, in the high-frequency region, of the reproduced signals. Thus, the use of a thin-lamination head in the play-back position avoids this second high-frequency attenuation. A system which employs a thick-lamination head in the recording position, and a thin-lamination head in the play-back position, should produce a fidelity superior to that of an arrangement in which a thick-lamination head is used in both the recording and the play-back positions. The fidelity superiority should correspond to an amount roughly proportional to the superiority of thin laminations over thick laminations. Such a comparison between the two systems was made.

Any difference between thin and thick laminations should show up to greater advantage in a test in which frequency response comparisons are made between thick laminations in both recording and play-back heads, and thin laminations in recording and play-back heads. High intensity of magnetization in the recording medium is necessary to raise the signal as far as possible above the noise level of the recording medium, and to eliminate the necessity for extreme amplification of signals appearing at the terminals of the play-back heads. This requirement demands a high-saturation-value material in the core of the recording head. Moreover, high-permeability material is required in the core of the play-back head, in order that the maximum flux be set up in the coil of the play-back head. However, at the time the test was made, thin laminations were available in only one material, high-permeability Mu-metal. This material has a low saturation value, rather than the high saturation essential for recording purposes in instances in which high flux density in the pole tip of the recording heads is needed to impress a high intensity of magnetization upon the recording medium. These restrictions prevented the use of thin laminations in the recording head, and thus confined their use to the play-back heads.

Throughout all tests reported in this paper the following test conditions prevailed:

Wire velocity = 5 feet per second
Bias frequency = 21 kc
Erase frequency = 20 kc
Recording and play-back air gap = 0.002 inch

Results

Figure 21 shows the fidelity response curve, taken with an automatic-level recorder, with a thick-lamination head in

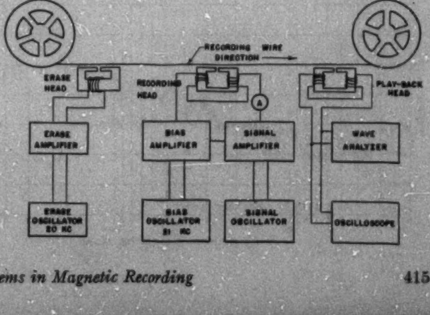


Figure 20. Block diagram of circuit used for obtaining fidelity characteristics

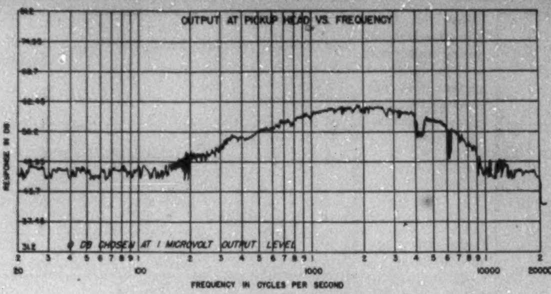

Figure 21. Thick-lamination head in play-back position

Bias current = 10 milliamperes
Signal current = 1.0 milliamperes

both the recording and play-back positions. The irregularities in the response were caused by local fluctuations in the magnetic properties of the recording wire, a characteristic possessed to a greater or lesser degree by all wires tested.

Figure 22 shows the frequency response of the thin-lamination head in the play-back position. The recording, made with the thick-lamination head, is the same one used to obtain the response curve of Figure 20, played through a thick-lamination head.

Observe that the response for the thin-lamination head holds at a high level up to 10 kc while the response for the thick-lamination head drops rapidly above 5 kc.

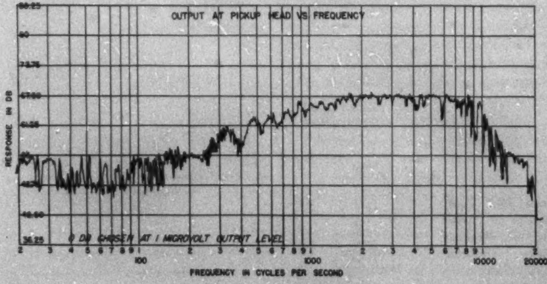
The response curve in Figure 22, taken with an automatic-level recorder, while not made from an identical recording, was made under the same operating conditions—with the same thick-lamination head in the recording position, the thin-lamination head in the play-back position and the same type of wire—as the response curve of Figure 13, taken with a wave analyzer. The same flatness of response in the region from 500 to 10,000 cycles per second is observed in both records.

None of the response curves shown in this paper were obtained with the aid of any inserted equalization whatever. The flat response of Figures 13 and 22 is caused by a fortuitous combination of the properties of the circuit components which are outlined in the mathematical background, and which may be analyzed in the manner outlined in preceding pages.

Except that the wire velocity, and bias and signal frequency ranges were the same, and that the thin-lamination head was used in the play-back position in both cases, the response curves of the Test-result Schedule Sheets of Figures 14 and 15 were made under test conditions, with circuit components differing from those used to obtain the response curves which show the superiority of thin-lamination heads over thick-lamination heads.

Figure 22. Thin-lamination head in play-back position

Bias current = 1.0 milliampere
Signal current = 1.0 milliampere



The wire-comparison-test response curves, combining circuit components having characteristics differing from those used in the thin-lamination test, do not exhibit the flat frequency response, but continue to rise until a sharp cut-off is reached. In every test, the superior high frequency response was obtained only when the thin-lamination head was used. It is evident that, while the contributions of all the other circuit elements may permit high-frequency response, the high-frequency region is attenuated unless thin laminations are used.

It was noted that, when the high-frequency response was improved by the use of the thin-lamination head, the high-frequency noise level was raised. Inspection of Figures 21 and 22, both made from the same recording, shows much more irregularity in the response of the thin-lamination head than in the thick-lamination head. It is concluded that the skin effect in the thick laminations attenuate the high-frequency noise components to the same extent that the high-frequency signal was attenuated.

Consideration of the theory of the demagnetization effect leads to the conclusion that a high-coercive-force recording medium tends to mitigate the demagnetization effect, and thus tends to raise the high-frequency response. A high residual induction tends to raise the over-all response level. Table I, obtained from the data of the comparison test of wires *A* and *B*, supports the theory.

Wire *A*, with the higher ratio of H_c to B_r, has its peak frequency occurring at the higher frequency, and possesses the lowest over-all amplitude. Wire *B*, with the lower ratio of H_c to B_r, has its peak frequency occurring at the lower frequency, and has the higher over-all amplitude.

Conclusions

For the purpose for which the analysis method was devised, it functions to give a more accurate and comprehensive understanding of the magnetic recording process than previous methods. It is recommended as a research method where a large mass of data must be collected and analyzed.

For an important experimental analysis of a magnetic recording system, a systematic investigation of fidelity characteristics throughout a reasonable wide range of operating conditions is necessary, if

Table I. Comparison of Wires A and B

	H_c Oersteds	B_r Gauss	Peak Fre-quency	Peak amplitude at 0.4 milliamperes signal current input
Wire *A*	400	1,350	10 kc.	3 millivolts
Wire *B*	245	8,100	6 kc.	20 millivolts

any degree of accuracy is to be expected from the experimental results. The trial and error method, adopted by some experimenters, is likely to leave unexplored some of the peculiar and, frequently, significant operating characteristics of a magnetic recording system. Usually, trial and error methods do not involve the keeping of a record of the trials, the errors, and the operating characteristics thus brought to light; the philosophy of systematic investigation is conducive to the keeping of written records.

The superiority of thin laminations over thick laminations is proved definitely. The Franklin Institute, under contract to the Special Devices Center, United States Navy, is constructing a series of recording and play-back heads to determine the extent to which it is necessary to go in the direction of using thinner laminations. It is expected that, with thin laminations in both recording and play-back heads, the superiority of thin laminations will be shown in greater contrast than is presented by the results shown here, in which only the play-back head employed thin laminations.

A method has been developed by which comparative response characteristics can be predicted from the known design, magnetic, and electrical properties of the recording heads, the play-back heads, and the recording media (wire or tape).

Symbols

B = magnetic induction

B_r = residual induction

B_d = remanent induction

e_0 = output voltage across a certain portion of the load impedance connected across the play-back head

e_1 = electromotive force of output coils of the audio transformer feeding the recording head

f = frequency in cycles per second

H = magnetizing force

H_c = coercive force

$M_1(\omega)$ = mutual inductance between the main coil of the recording head and an exploring coil wound on a pole tip

N_1 = number of turns in the recording coil

N_2 = number of turns in the play-back coil

N, S = conventional symbols to indicate magnetic polarity

t_1, t_2, t_3 = instantaneous times in process of recording sine wave on recording medium

The function, $h_1(\omega)$ = an expression representing the flux in the recording head as a function of ω under conditions of constant current and for a given lamination thickness. The variation of flux with frequency is referred to as the magnetic skin effect

The function, $h_2(\omega) = h_2'(\omega) \times h_2''(\omega)$. This quantity gives the flux threading the coils of the play-back head as a function of magnetic skin effect and the air-gap dimensions of the play-back head

The function, $h_2'(\omega)$ = the expression for the skin effect in the play-back head

The function, $h_2''(\omega)$ = an expression for the influence of the relation between effective magnet length and air-gap dimensions in the play-back head

The function, $L_1(\omega)$ = inductance of the recording head as a function of frequency

The function, $L_2(\omega)$ = inductance of the play-back head as a function of frequency

The function, $m(\omega,v)$ = a quantity expressing the remanent flux in the recording medium as a function of ω and velocity, the combination of which determines the effective magnet length; referred to as the demagnetization effect

The function, $R_1(\omega)$ = the effective resistance of the recording head as a function of frequency

The function, $R_2(\omega)$ = the effective resistance of the play-back head as a function of frequency

The function, $Z_0(\omega)$ = the total load impedance across the play-back head

The function, $Z_0'(\omega)$ = that part of $Z_0(\omega)$ across which the output voltage e_0 is taken for amplification

The function, $Z_1(\omega)$ = impedance in recording circuit external to recording head as a function of frequency

$\theta = \tan^{-1} B/H$

λ = wave length of recorded signal

ϕ = flux

ϕ_1 = flux in recording-head air gap effective in magnetizing recording medium

ϕ_m = flux surrounding the fixed magnets in the recording medium

ϕ_2 = flux produced in core of play-back head by passage of recording medium across head

$\omega = 2\pi f$

No Discussion

Considerations on Facsimile Transmission Speed

HENRY F. BURKHARD
NONMEMBER AIEE

PROBABLY one of the most pressing problems facing facsimile engineers is the requirement for greater speed of transmission. Several approaches to the problem have been made; namely, special scanning methods, improvement of means of modulation and demodulation, more efficient use of the frequency channel available, and the use of wider channels.

The speed of transmission of a facsimile copy depends upon the usable bandwidth of the available channel, the size of copy, and the definition required to adequately define the intelligence on the copy. Since scanning of large uniform areas results in the generation of low phototube signal frequencies which cannot be transmitted directly over most communication channels, the phototube signal must be used to modulate an audio-frequency carrier. Selection of the carrier is based upon the usable channel and the maximum phototube, or keying frequency which must be placed upon the carrier. The main item, therefore, which determines the speed of transmission, is the maximum keying frequency. This is a somewhat fictitious figure based upon the scanning of alternate black and white lines equal in width to the definition of the system as shown in Figure 1. Here the aperture is assumed to be a square also equal to the definition. The phototube signal is triangular and may be expanded into the Fourier series

$$F(t)=E+\frac{8}{\pi 2}E\left(\cos\frac{2\pi t}{T}+\frac{1}{9}\cos\frac{3(2\pi t)}{T}+\right.$$
$$\left.\frac{1}{25}\cos\frac{5(2\pi t)}{T}+\dots\right)$$

It is not anticipated that frequencies above the fundamental need be transmitted. The fundamental, therefore, is selected as being the maximum keying frequency. For present military equipment, this frequency is 900 cycles per second.

On normal copy, the sequence of lines shown seldom occurs. Usually spacing of lines is irregular, and large patches of white, gray, or black may be found. From a purely theoretical viewpoint, some advantage might be gained if the modulating frequency were a constant and were equal to the maximum modulating frequency. The significance of this may be determined from the two lower sketches of Figure 1 where various widths of light and dark areas are assumed. If the time required to scan from *a* to *b* is 1/1,800th second, the time required to scan from *b* to *d* should also be 1/1,800th second. This implies a much higher rate of scanning speed for the wider areas and lines. Preferably the scanning should take place in almost 1/1,800th second from *b* to *c* and then very rapidly from *c* to *d* in the order of 1/50,000th second. Although the side-band frequency would be a constant, the transmission of synchronizing signals such as a keyed tone would be necessary. The rapid acceleration of the scanning system would not be too fantastic if electronic scanning beams were employed.

Since most facsimile systems, however, are mechanical, this theoretic type of scanning cannot be realized. Probably the closest approach is the teleautograph system. In that system, a scribe is manipulated by the operator at the transmitting end so that the message to be transmitted is traced. Information on the orientation of the scribe is transmitted either by transmitting the *x* and *y* coordinates or by starting at a given point and transmitting relative motion. A pencil at the receiving end automatically follows the transmitting scribe. It is also necessary to transmit pencil-up and pencil-down information. This is a scanning type of system with almost all of the scanning taking place along the intelligence being transmitted. This results in relatively low modulating frequencies. It has the decided disadvantage that a transmitting operator must write out or trace the message, and therefore, the speed of transmission is limited. Practically all facsimile scanning, however, is not of this type but is sequential such as the scanning of a copy on a rotating drum by means of an optical system which slowly progresses parallel to the axis of the drum. One suggestion which has been made for increased speed on such a system is the use of specially-shaped letters and figures designed for the generation of a minimum[1] modulating frequency. This method is satisfactory for special cases, but the limitation caused by the requirement for a special typewriter and the impossibility of transmitting maps and sketches has discouraged general use.

Paper 49-108, recommended by the AIEE communication committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted November 27, 1948; made available for printing December 21, 1948.

HENRY F. BURKHARD is a facsimile design engineer with the Signal Corps Engineering Laboratories, Fort Monmouth, and is assigned to the Coles Signal Laboratory, Red Bank, N. J.

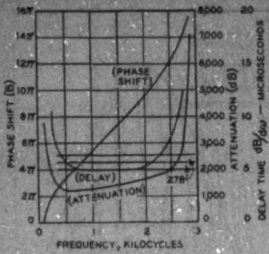

Figure 2. ***CF-1-B*, channel 1, and 20 miles "spiral four" cable**

A second approach on increasing the speed is through the more efficient use of the available frequency channel. Consider a channel having characteristics as shown in Figure 2. The pass band for ordinary use would be considered to be from 200 to 2,600 cycles per second. For facsimile, however, the usable portion of the band is limited by the delay distortion and is generally less than the pass band indicated by the attenuation curve. If the time of transmission through the system were the same for all frequencies, there would be no phase or delay distortion. The relation between phase shift, time delay, and frequency would be

$$B=\omega T$$

where

B = phase shift in radians
$\omega=2\pi f$
T = time delay in seconds

In actual transmission systems, however, the foregoing ideal condition is rarely found. For practically distortionless transmission of signals, it is necessary that the transfer impedance of the system have a constant amplitude and a phase angle linearly proportional to frequency with a phase angle value of $n\pi$ at zero frequency, where n = 0, 1, 2, 3, 4.... The phase shift relation then is

$$B=\omega t+n\pi$$

The value t represents the time it requires for the signal, or envelope, to travel through the transmission medium whereas the time required for various steady-state single frequencies to be transmitted is given by the total phase shift in radians at that frequency, divided by 2π times the frequency.

$$T=\frac{B}{2\pi f}$$

When the constant n has a value which is not an integer, a distortion sometimes called intercept distortion occurs. This distortion has little or no effect on the envelope wave shape. For a nonlinear relation between the phase shift and frequency, the envelope delay time at each frequency is given by $dB/d\omega$ and can, therefore, be found from the slope of the phase angle versus frequency curve. The acceptable limit for delay distortion is usually stated as an allowable number of microseconds plus or minus from the mean delay time of the envelope. This limit must be met over the frequency range required for the transmission. The figure generally used in the art has been ± 250 microseconds per 1,000 cycles of modulating frequency. Based upon a modulating frequency of 900 cycles, the limit for present military facsimile equipment would be found from 250 × 1,000/900 to be ± 278 microseconds. These limits have been superimposed in Figure 2 on the characteristics for the *CF-1-B* carrier channel and show a usable range for facsimile of about 900 to 2,300 cycles. Under Signal Corps contract for investigation of high-speed facsimile transmission, Radio Corporation of America engineers, Maurice Artzt and Charles Young, included study of the delay distortion requirements. The figure of ±250 microseconds per 1,000 cycles of modulating frequency was confirmed by tests employing vestigial sideband transmission. Of interest was the fact that when the curve of delay distortion versus frequency was irregular, a greater tolerance on delay distortion could be permitted if the carrier frequency were specially placed in the band. For a modulating frequency of 1,000 cycles, a carrier frequency (fc), and vestigial side band width (fv), the delay distortion over the band from (fc − fv) to (fc + fv) must not exceed ±250 microseconds. Outside this band of frequencies and out to the limit (fc−1,000), if the lower side band is being transmitted, or to (fc+1,000) if the upper side band is transmitted, the delay distortion must not exceed ±500 microseconds. The phase distortion limits for other maximum modulating frequencies are found from

Permissible delay distortion

$$=\frac{\text{(delay distortion at 1,000 cycles)}}{\text{modulating frequency in kilocycles}}$$

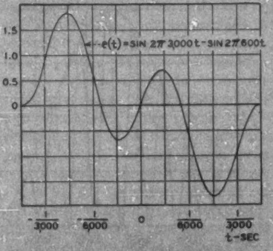

Figure 3. Single sideband signal

3,000 cycle carrier, 2,400 cycle modulation, carrier suppressed 6 decibels

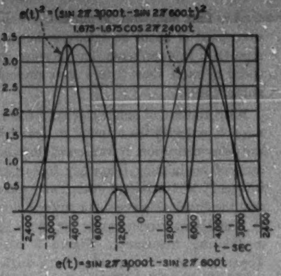

Figure 4. Full-wave square-law detected single sideband signal

Facsimile designs are always based upon available transmission channels and the delay distortion to be expected. Commercial lines used for speech have either no phase correction, or if they are corrected for delay distortion, the amount of correction is insufficient to be of appreciable value for facsimile. The exception to this is the case of a line leased specifically for picture transmission. Such a line is a standard voice channel specially corrected to decrease the delay distortion. In addition to the monetary consideration of such a line, there is the length of time often necessary to accomplish the delay correction. For military equipment intended for wire line transmission, therefore, the speed of transmission has been kept low to permit operation over normal uncompensated voice circuits. For a definition of 96 lines per inch, this has resulted in a scanning speed of about 12 square inches per minute. Due to integrated planning on the part of high military technical officers and engineers, the future military transmission channels are being designed with a view towards voice, teletype, and facsimile transmissions. Attempts are to be made to base initial designs of the channels on suitable phase as well as attenuation characteristics. This program prompted the study and establishment of phase distortion limits. It is expected that the available military channel will be from 300 to 3,500 cycles per second, and the aim will be to restrict the variation in envelope delay time of all frequencies in the range of 600 to 3,200 cycles per second to no more than ±100 microseconds from the mean delay time. This limit will permit a transmission speed of about 26 square inches per minute. It represents an increase in speed of more than 2 to 1 over present military sets.

With the use of single sideband transmission and with the attempt to diminish the delay distortion, it was found that the ratio of modulating frequency to carrier frequency was increased to such an extent that the envelope wave shape suffered due to insufficient carrier cycles per cycle of modulating frequency. Figure 3 and Appendix I show a sine wave with single sideband modulation where the modulation frequency is 4/5ths of the carrier frequency, and the carrier is attenuated 6 decibels. Figure 4 shows the result of full-wave square-law detection of the above wave; the envelope wave shape is very poorly defined. Artzt and Young of RCA Laboratories have evolved a method of demodulation based upon separating the wave into two parts and shifting components of one part of the wave forward and of the other part back 45 degrees. This is accomplished by heterodyning one portion of the wave with a sine wave and the other with a cosine wave. Each part is then detected by full-wave square-law detection and the two outputs superimposed, Appendix II. The sum of the two quarter phased signals is seen in Appendix III to add up to the modulating signal of $2-2\cos 2\pi 2{,}400t$.

Another modulating and demodulating system was devised by engineers of Radio Inventions, Inc. The scanner operates at a speed resulting in 2,400-cycle modulating frequencies. A carrier frequency of 10 kc is used giving a very satisfactory ratio of modulating to carrier frequencies. A filter in the output of the ring modulator which is employed eliminates most of the low sideband frequencies. The resulting signal is heterodyned with a 13-kc tone, thereby generating 23-kc and 3-kc carriers. By means of a special low-pass filter, only the lower carrier and its single sideband frequencies are selected for transmission over a line. At the receiver, the 600 to 3,000-cycle signal is heterodyned with a 13-kc signal as shown in Figure 5 in order to place the modulation back on a 10-kc carrier. Figure 6 shows the envelope of the 2,400-cycle modulation to be adequately defined by the full-wave rectified pulses of the carrier.

When some modulating methods such as the bridge modulator used by Times Facsimile Corporation are employed, the output signal from the modulator contains the modulator frequency, the carrier frequency, and sum and difference frequencies. The components proportional to the modulating frequency represent distortion of the modulated signal and will cause echoes due to delay distortion in the transmission medium. It is usually necessary, therefore, to eliminate the modulating frequencies from the transmitted signal by a filter. When the ratio of modulating to carrier frequency is less than one-half, the use of low-value coupling capacitors in the amplifier provides sufficient filtering action. When the ratio is increased, however, the use of filtering methods becomes more and more difficult. The Times Facsimile Corporation has recently perfected and adopted a revised modulating method. Referring to Figure 7, it is seen that the normal cell circuit at "*a*" generates a distorted wave. When light is applied to the phototube, the resistance of the cell drops, the capacitance increases, and a voltage is generated proportional to the so-called picture or keying frequency. It is this latter voltage which causes the distortion. The newer system contains a special phototube RCA type *5652* developed specifically for the purpose. It contains two emitting surfaces and is used in a circuit with practically no d-c anode bias. When light is applied to the phototube, the emissions from each cathode, which are caused directly by the light energy, produce an a-c voltage on the grid of the following tube instead of a pulsating d-c signal. A more symmetrical signal is produced as shown. In order to permit ready change from positive to negative types of modulating, the system has been worked into the normal Times Facsimile Corporation bridge-modulator circuit shown at "*c*."

A closer examination of the characteristics of the modulating-frequency signal is of interest. As mentioned previously, the allowable delay distortion is equal to ±250 microseconds per 1,000 cycles of

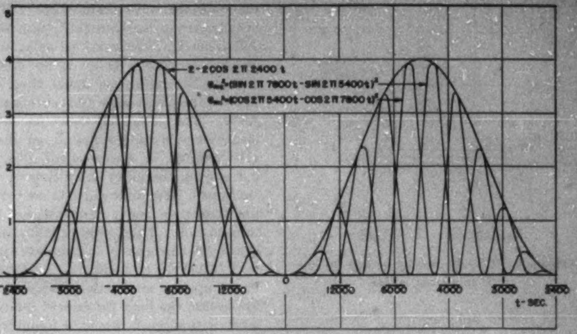

Figure 5. Heterodyne method of detection

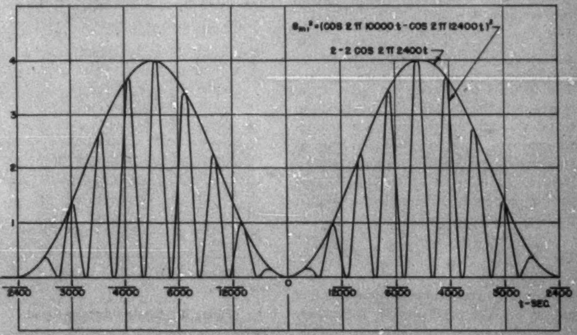

Figure 6. Heterodyne detection method

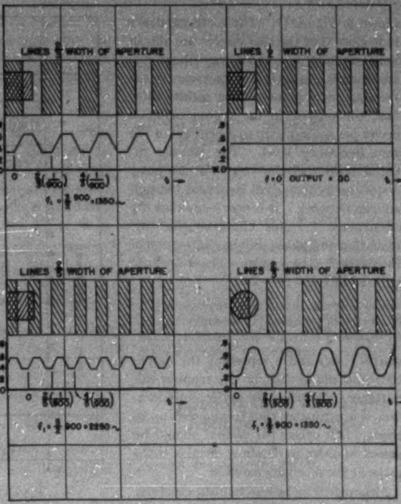

Figure 8 (right). Scanning of various line sequences

modulating frequency. This modulating frequency is computed on the basis of scanning alternate black and white lines where the width of the lines is equal to the definition of the equipment. Usually the aperture size is also equal to the definition. Under such conditions, the modulating wave shape as shown previously in Figure 1 is triangular with the Fourier series expansion shown. The fundamental of the series is considered usually to be the maximum frequency which must be transmitted. Naturally an improved wave shape would result if the harmonics were also transmitted, but this is not permissible due to the necessity to conserve bandwidth. In actual practice, the scanning of alternate black and white lines equal to the definition does not generate the maximum frequency. If the lines and spaces being scanned are not as wide as the aperture, higher frequencies are generated. Figure 8 shows various widths of recurring lines and spaces. When the line width and space width are each two-thirds of the aperture size, the wave shape is trapezoidal. A Fourier analysis results in a fundamental frequency of $1^1/_2$ times as much as for the case where the lines, spaces, and aperture were the same width. An interesting case occurs when the scanning lines and spaces are equal to one-half of the aperture. The output theoretically is pure direct current. This might be utilized as a means for measurement of the aperture size of a transmitter. Aperture distortion and halo, however, will add a slight ripple to the direct current. When the lines and spaces are two-fifths the width of the aperture, the fundamental frequency is five-halves the frequency of the case where lines, spaces, and aperture are equal. With the circular aperture, the wave shape is different, but the fundamental frequency is the same as for the square aperture. Naturally the special d-c case found for the square aperture is not encountered with the circular aperture. Normally facsimile systems are not designed to transmit lines finer than the aperture width, and reproduction of the finer lines considered before is not expected.

The second condition which involves additional frequencies from those which result from the scanning of alternate black and white lines is the scanning of isolated pulses. Two analytical methods will show the frequency distribution of the distribution of the components to be encountered. In both cases the line or spot to be scanned will be assumed to be equal to the width of the square aperture. Scanning will result in a linear rise and fall of signal, resulting in a triangular signal wave shape. The first method is to assume that the pulses occur repetitiously but are spaced a considerable distance apart. A standard Fourier series representation of the pulse may be found, Figure 9. For the military facsimile set *AN/TXC-1* with a single line on the copy, the repetitious rate is once a second, and width of pulse is 1/900 of a second. Using the formula and Figure 3 to be found on page 22 of the Radio Engineers' Handbook,[2] $2\pi k$ represents 1/900 of a second and $k=1/900$. A plot of the coefficients is also shown in Figure 9. The fundamental frequency is one cycle per second. It is to be noted that in the vicinity of 1,800 and 3,600 cycles per second, the output is zero.

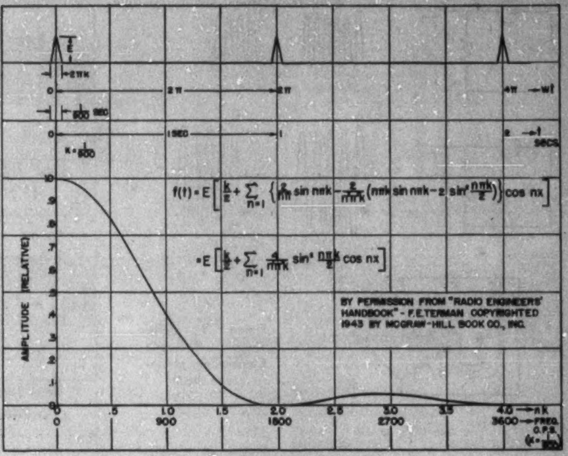
A second more versatile analysis is to use the Fourier integral, as shown in Figure 10. Here the dot being scanned is assumed to be completely isolated from other dots and lines on the copy. Therefore, all transients resulting from scanning the dot will die away before the scanning of other dots. The equations of the two straight lines are found first. These give a description of the original pulse as a function of time. The frequency spectrum of the pulse is found from the equation

$$F(\omega)=\frac{1}{2\pi}\int_{-\infty}^{\infty} f(t)e^{-j\omega t}dt$$

As noted in Figure 10, the time function is substituted in the integral and by integrating term by term the result

$$F(\omega)=\frac{1{,}800E}{\pi}\left[\frac{1-\cos\frac{\omega}{1{,}800}}{\omega^2}\right]$$

is found. This represents a continuous frequency spectrum. In order to find the value at zero frequency, it was necessary to expand the cosine function before substituting $\omega=0$. A plot of this superimposed upon the Fourier series result is



BY PERMISSION FROM "RADIO ENGINEERS' HANDBOOK" - F.E.TERMAN COPYRIGHTED 1943 BY MCGRAW-HILL BOOK CO., INC.

Figure 9. Scanning of widely separated thin lines

shown in Figure 11. The correspondence is so close that the two curves are almost indistinguishable. The very slight discrepancy is probably due to errors in extrapolation of points. The results show that the output in the region of 2,500 cycles per second is up to 5 per cent of the zero frequency level. The Fourier integral result permits study of the pulse distortion as the signal is passed through a given network. It is necessary that the admittance transfer characteristic (attenuation and phase shift) as a function of the frequency be known. These are substituted in

$$f(t) = \int_{\infty}^{\infty} F(\omega)\, Y(\omega) e^{i\omega t + a} d\omega$$

where $Y(\omega)$ and a represent the amplitude and phase shift of the transfer admittance. For the case under consideration, it is estimated that frequencies up to about 1,000 cycles per second should be passed in order to obtain a suitable wave shape at the receiving machine.

Although it appears that the analysis based upon scanning of alternate black and white lines equal to the aperture size is not adequate, it must be remembered that almost all applications of the results are based upon empirical data. For example, the figure of ±250 microseconds of delay distortion per 1,000 cycles of modulating frequency which is tolerable, was based upon actual test where the 1,000 cycles of modulating frequency really is a statement of linear scanning speed. Similarly the maximum modulating frequency allowable for a given carrier frequency was an empirical value found from actual test. The modulating frequency for any given definition, therefore, represents a maximum linear scanning speed which is tolerable. This factor coupled with the difficulty involved in solving the Fourier integrals for a given network have led most facsimile engineers to use the alternate line method of analysis.

The foregoing attempts to utilize more efficiently the available frequency spectrum of a voice circuit may at best produce about a $2^1/_2$-to-1 increase over the scanning speed of present military equipment. As facsimile transmissions assume more importance, this increase in speed may not be sufficient, and it is expected that the use of wider band channels will become imperative. Study of the problem was, therefore, undertaken by the Radio Corporation of America under a Signal Corps contract. This study was broken down to cover transmissions over channels 16-, 48-, 96-, and 192-kc wide. The limiting factor on the transmission speed was determined to be the delay distortion expected over practical carrier communication circuits. The requirement for the 16-kc channel is ±30 microseconds, for the 48-kc channel 11 microseconds, the 96-kc channel 5.5 microseconds, and the 192-kc channel ±2.75 microseconds. It is seen that as the spectrum is widened not only does the delay requirement become more stringent, but these tighter limits must be held over a wider frequency band. In addition to the excessive delay requirements for the two widest channels, it is not practical with ordinary techniques to record in daylight at the speeds of 333 and 667 square inches per minute which the channels permit. To ease both of these requirements, recording on wet electrolytic paper will be employed using several wires wrapped helically and spaced equidistant around the drum. (This method was first suggested to the Signal Corps Engineering Laboratories by engineers from Radio Inventions, Inc., and subsequently during discussions with engineers from RCA Laboratories.) The damp paper passes between the drum and a straight edged

---

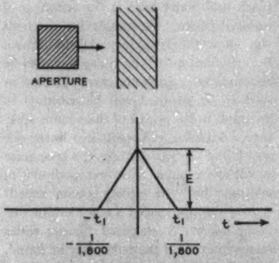


Figure 10. Frequency spectrum generated by scanning isolated spot

from

$-\infty t_0 - t_1\ F(t) = 0$
$-t_1$ to 0 $F(t) = 1{,}800Et + E$
0 to t_1 $F(t) = -1{,}800Et + E$
t_1 to ∞ $F(t) = 0$

The frequency spectrum is found by means of the Fourier Integral

$$F(\omega) = \frac{1}{2\pi}\int_{-\infty}^{\infty} F(t) e^{-i\omega t} dt$$

$$F(\omega) = \frac{1}{2\pi}\int_{-} (1{,}800Et + E) e^{-i\omega t} dt + \frac{1}{2\pi}\int_{0}^{t_1} (-1{,}800Et + E) e^{-i\omega t} dt$$

$$F(\omega) = \frac{E}{2\pi}\left[\int_{-t_1}^{0} 1{,}800te^{-i\omega t} dt + \int_{-t_1}^{0} e^{-i\omega t} dt - \int_{c}^{t_1} 1{,}800te^{-i\omega t} dt + \int^{t_1} e^{-i\omega t} dt\right]$$

$$F(\omega) = \frac{1{,}800E}{\pi}\left[\frac{1 - \cos\frac{\omega}{1{,}800}}{\omega^2}\right]$$

bar which presses the paper against the helices. As the drum rotates, the point of contact between the bar and any one helix wire progresses to the right. For the 48-kc channels, one helix wire will be used, and the drum will revolve at 2,500 rpm. One 8 by 10 inch copy will be printed every half a minute.

For the 96-kc transmission, the channel will be divided into two 48-kc channels. By means of dual scanning systems spaced 180 degrees apart, two lines of the original copy will be scanned simultaneously, and the signals from each photocell placed upon an appropriate carrier in each of two 48-kc bands. At the receiving end, two of the helices will be employed, spaced half way around the drum from each other. The bar will make contact with both helices simultaneously. Each band will supply the signals for one helix, and therefore, two scanning lines will be printed concurrently. The chief advantages are that the delay distortion over each 48-kc channel need only be held to ±11 microseconds instead of the requirement that the delay distortion over the wide 96-kc channel be ±5.5 microseconds. In addition, each helix wire need only print at the same rate of speed as in the case where the whole channel was 48-kc wide. Therefore, the actual linear speed of recording for each scanning line has not been increased. The recording power has been doubled because two lines are printed simultaneously, but the drum speed remains the same, 2,500 rpm. An 8 by 10 inch copy will be produced every 15 seconds.

The 192-kc channel likewise will be split into four 48-kc channels. Four scanning heads 90 degrees apart will be used for the transmitter, and four helices will be used at the recorder. Drum speed remains at 2,500 rpm, but an 8 by 10 inch copy will be produced every 7.5 seconds.

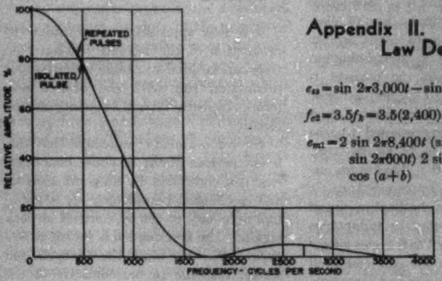

Figure 11. Frequency spectrum for short triangular pulses

Appendix I. Single Sideband Scan

Assume cosine modulation with zero initial phase shift

$$e=E(1-\cos 2\pi f_k t)\sin 2\pi ft$$

$$e=E\sin 2\pi ft-E\cos 2\pi f_k t\cdot\sin 2\pi ft$$

$$2\sin a\cdot\cos b=\sin(a+b)+\sin(a-b)$$

$$\cos 2\pi f_k t\cdot\sin 2\pi ft={}^1/_2\sin(2\pi ft+2\pi f_k t)+{}^1/_2\sin(2\pi ft-2\pi f_k t)$$

$$e=E\sin 2\pi ft-E/2\sin 2\pi(f+f_k)t-E/2\pi\sin 2\pi(f-f_k)t$$

For single sideband transmission, the carrier is usually attenuated 6 decibels. Assume that the upper sideband is eliminated.

$$e_{ss}=E/2\sin 2\pi ft-E/2\sin 2\pi(f-f_k)t$$

If, $f=3{,}000$, $f_k=2{,}400$, and $E=2$

$$e_{ss}=\sin 2\pi 3{,}000t-\sin 2\pi 600t$$

Appendix II. Quarter Phased Law Detection

$$e_{ss}=\sin 2\pi 3{,}000t-\sin 2\pi 600t$$

$$f_{c2}=3.5f_k=3.5(2{,}400)=8{,}400\text{ cycles}$$

$$e_{m1}=2\sin 2\pi 8{,}400t\,(\sin 2\pi 3{,}000t-\sin 2\pi 600t)\quad 2\sin a\cdot\sin b=\cos(a-b)-\cos(a+b)$$

$$e_{m1}=\cos 2\pi 5{,}400t-\cos 2\pi 11{,}400t-\cos 2\pi 7{,}800t+\cos 2\pi 9{,}000t$$

$$e_{m2}=2\cos 2\pi 8{,}400t\,(\sin 2\pi 3{,}000t-\sin 2\pi 600t)\quad 2\cos a\cdot\sin b=\sin(a+b)-\sin(a-b)$$

$$e_{m2}=\sin 2\pi 11{,}400t-\sin 2\pi 5{,}400t-\sin 2\pi 9{,}000t+\sin 2\pi 7{,}800t$$

If upper terms are removed by filtering

$$e_{m1}=\cos 2\pi 5{,}400t-\cos 2\pi 7{,}800t$$

$$e_{m2}=\sin 2\pi 7{,}800t-\sin 2\pi 5{,}400t$$

The demodulated wave $=e_{m1}^2+e_{m2}^2$

$$=(\cos 2\pi 5{,}400t-\cos 2\pi 7{,}800t)^2-(\sin 2\pi 7{,}800t-\sin 2\pi 5{,}400t)^2$$

This derivation is based upon the quarter phased method of detection proposed by Maurice Artzt and Charles Young of the RCA Princeton Laboratory.

Appendix III. Heterodyne Method of Detection

$$e_{ss}=\sin 2\pi 3{,}000t-\sin 2\pi 600t$$

$$e_m=2\sin 2\pi 13{,}000t\,(\sin 2\pi 3{,}000t-\sin 2\pi 600t)\quad 2\sin a\cdot\sin b=\cos(a-b)-\cos(a+b)$$

$$e_m=\cos 2\pi 10{,}000t-\cos 2\pi 16{,}000t-\cos 2\pi 12{,}400t+\cos 2\pi 13{,}600t$$

If the upper terms are removed by filtering

$$e_m=\cos 2\pi 10{,}000t-\cos 2\pi 12{,}400t$$

This is full law square law detected

$$e_m^2=(\cos 2\pi 10{,}000t-\cos 2\pi 12{,}400t)^2$$

This derivation is based upon the heterodyne method of detection proposed by engineers of Radio Inventions Incorporated.

Discussion

R. W. Carlisle (Sonotone Corp., Elmsford, N. Y.): Burkhard's paper is a thorough résumé of the painstaking efforts of many investigators and it aggressively assembles their findings into one efficient facsimile system.

In connection with the scanning of facsimile print by sequential means, Burkhard has mentioned the writer's suggestion of using specially-shaped letters and figures designed for the generation of a minimum modulating frequency.*

This method consists of a series of steps:

> A typewriter roll is fitted with sprocket teeth at each end in the same manner as in various bookkeeping machines.
>
> A bold Gothic alphabet is used with a few of the letters re-shaped to emphasize certain portions for easy scanning.

The material to be transmitted is typed on this machine, using paper having sprocket holes along the edges.

This paper is then attached to a facsimile scanner equipped with pins to hold it in such an alignment that the scanning spot will exactly traverse the top and bottom edges and other predetermined bands in each line of type. The increase in scanning efficiency is well over 2 to 1, and may be estimated by study of relative shapes of type.

The use of this system does not put any restrictions on the use of the scanner for other material such as maps and sketches. Conversely, however, a facsimile system which has been designed for optimum transmission conditions will obviously be most efficacious for transmitting typed matter by this system.

Control Chart Methods Applied to Frequency Response Curves

A. B. MUNDEL
MEMBER AIEE

IT IS the purpose of this paper to present an application in which statistical control chart technique has assisted in the manufacture of an electro-acoustic transducer. The operation of a transducer will be described as well as the engineering considerations required before control chart techniques can be applied.

The use of control charts has been widely shown for maintenance of mechanical dimensions. The same techniques can be applied to obtain uniform frequency response curves from transducers. Not only does production benefit by reduced scrap and rework, but in addition a more uniform product is obtained.

Furthermore, two types of specifications will be discussed. First, the point by point system in which the response is specified at each frequency. Secondly, the sensitivity and frequency response shape system in which the sensitivity at a single frequency is specified, and the shape of the response curve is given using the response at the specified frequency as a reference level. Data obtained on an insert receiver will be presented to show the conditions under which each form of specification is preferable.

The Insert Receiver

The midget receiver shown in cross-section in Figure 1(a) will be discussed. It is desirable to maintain a high degree of uniformity both in sensitivity and in frequency response. The frequency characteristic of this receiver is shown in the conventional manner in Figure 2, which shows the response of three typical units.

Fundamentally, a receiver consists of a magnetic assembly which drives a diaphragm. The alternating current in the coil on the pole piece causes a variation in the magnetic flux which alternately assists and opposes the action of the "flux linkages" through the permanent magnet, the air gap, and the diaphragm and armature assembly, resulting in the vibration of the diaphragm. Vibration of the diaphragm gives rise to sound or acoustic energy.

At low frequencies the amplitude of vibration is governed by the total stiffness of the vibrating system. This stiffness is not only that of the diaphragm but also of the chambers V_1 and V_2. Acoustical engineers frequently make use of electrical circuit notation to assist in the analysis of vibrating system behavior. An electrical analog of the receiver is shown in Figure 1(b). The compliance or inverse stiffness of the chambers V_1 and V_2 (Figure 1(a)) is represented by the capacitances C_1 and C_2 in Figure 1(b). The compliance of the diaphragm assembly is represented by capacitance C_3. The equivalent mass of the diaphragm and armature are represented by inductance M_1. At approximately 1,200 cycles a resonance occurs between the stiffnesses and the mass of the diaphragm and armature. The sharpness of this resonance is controlled by an acoustic damping element placed in the receiver cap. At frequencies above this resonance another resonance occurs, due to the Helmholtz resonator effect occurring in the chamber immediately over the diaphragm. The acoustic compliance of chamber V_2 is represented by the capacitor C_2 which resonates with the mass of a slug of air moving in and out of the constricted area in the nub of the receiver and the tube connecting it to the 2-cubic centimeter chamber. This mass is shown as M_2 in the equivalent circuit. When measuring the acoustic sensitivity the receiver is driven at a constant power level by a signal generator and matching network. Acoustic output is measured by a calibrated microphone in a 2 cubic centimeter chamber connected to the receiver.[1] The compliance of this measuring chamber is represented by the capacitance C_4 in the electrical analog. The compliance of C_4 is sufficiently large to have little effect on the frequency characteristic. The measurements used in this discussion have all been obtained on a system such as shown in Figure 1(a). The units of measurement are decibels (db) above an arbitrary reference level.

It should be clear that this paper does not describe a new development in receiver design, but mainly the application of a production tool that simplifies the task of obtaining the desired qualities in the completed product.

Production Control of the Insert Receiver

It is now appropriate to consider the production of the receiver. What controls can be used to obtain a continuous production run with the desired uniformity, sensitivity, and frequency characteristic?

We have already indicated that different regions of the response characteristic are controlled by different acoustic and mechanical parameters. It is therefore necessary to set up controls at each region. The first control is set up at 400 cycles. We have found the 400 cycles per second response to be indicative of the general sensitivity of the receiver. This frequency is chosen for convenience; it would have been as effective to use 200 or 300 cycles per second as a control point. The sensitivity at 400 cycles is a function of the magnetic circuit performance, the air gap and the net stiffness of the system.

To find what level of sensitivity is

Paper 49-109, recommended by the AIEE communications committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted November 10, 1948; made available for printing January 7, 1949.

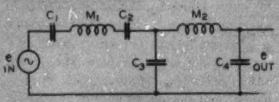

Figure 1(b). Electrical analog of vibrating system of receiver

maintained and to assist in the choice of corrective action if necessary, five sample receivers are taken at regular 2-hour intervals and measured for acoustic sensitivity. The average response and the range of the five samples at 400 cycles per second is plotted in Figure 3. The range is the difference between the maximum and minimum response of the sample of five. (Standard notation uses the symbols $\bar{X}$ and R for the average and range.) Figure 3 shows a control chart in which 19 samples of five have been taken and the average $\bar{X}$ and range R plotted. The grand average $\bar{\bar{X}}$ and the average range $\bar{R}$ also have been indicated. This chart is similar to the forms recommended in the ASTM Manual on the Presentation of Data, which contains a more complete discussion on applications of statistical techniques to engineering problems.[3]

Control limits for the averages and ranges are indicated by the dotted lines and are computable from the grand average and average range plus the factors A_2, D_3 and D_4 given in Table I of the previous reference. The points on the graph of Figure 3 should all lie within the indicated control limits if the process represented approximates a symmetrical bell-shaped frequency distribution as shown at the left of Figure 3. If all points do not lie within control limits there is evidence of variations due to assignable causes rather than to pure chance. A point outside of the control limits indicates that at least one controlling factor has changed. At this frequency (400 cycles per second) we must check the magnetic circuit, net stiffness, and air gap. We have found that these parameters are likely to drift in production unless watched in this manner, and that points outside of control limits are indicative of one or more of these items passing out of limits.

A histogram of the individual readings is shown at the left of Figure 3. The individuals, of course, have a wider variation than the averages shown on the control chart at the right of the figure. In the type of frequency distribution which we encounter so frequently (that is, a symmetrical bell-shaped normal distribution) we can expect about 99.7 per cent of the observations to occur within an interval extending 3σ units on each side of the average. A satisfactory estimate of σ can be obtained from the relation $\sigma = \bar{R}/d_2$. (Values of d_2 can be found in Table I, of the ASTM Manual).[3] Figure 3 shows a very satisfactory situation engineering-wise in that the entire production is well within the specification limits.

The next section at which a control chart (Figure 4(a)) is applied is at the first resonance. Since the first resonance occurs in the mesh containing the effective mass of the diaphragm and the effective stiffness of the vibrating system, variations in the frequency of this resonance are likely to occur simultaneously with variations in the low-frequency sensitivity. Increased stiffness is likely to result in lower sensitivity and higher resonance, as may be readily seen with reference to the equivalent circuit. The amplitude of this first peak is recorded on another control chart, Figure 4(b). The amplitude is a function of the damping rather than of the parameters mentioned previously. Excess peak amplitude can be corrected by increasing the acoustic damping which is placed at the entrance to the nub, as shown in the crossectional view.

To extend the frequency range of transducers, it is common practice to use auxiliary acoustic parameters effective at the high-frequency end of the spectrum. An example of this is the second peak which is due to the acoustic resonance occurring in the second mesh. This is controlled by the stiffness of the volume V_3 and the mass of the slug of air in the orifice previously referred to in the electrical analogue as C_3 and M_2 respectively. Variations in frequency of this resonance are usually due to variations in the clearance between the diaphragm and the cap. The control chart offers an effective means of watching this effect. Charts are kept as in Figure 4(c). The second resonance frequency is affected to a certain degree by its proximity to the first resonance. If the first and second resonances are too far apart, there will be a deep trough between. If this is worth watching, a control chart also may be set up as in Figure 4(e) and (f), using a pair of charts for valley frequency and amplitude. This is an effective method of checking the resonance peak separation. The amplitude of the peak of the second resonance control chart, Figure 4(d) is significant. High values usually correspond to low-resonant frequency. Conversely, low values of amplitude at this peak may be due to high frequencies of resonance but are more likely to occur when the cap and body are not effectively sealed together, or when there is an external leak from the volume V_3.

In selecting the data to be plotted on a control chart, it is essential to decide on regions that are important insofar as the applications are concerned and on regions which indicate what corrective action is appropriate. In our factory we have used these methods to warn us when variations in receiver manufacture occur.

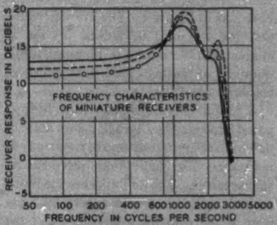

Figure 2. Typical frequency response of miniature receiver

Composite Curve of Receiver Response

By referring to the frequency characteristics of the midget receiver, Figure 2, it is apparent that plotting many curves on one sheet will cause endless confusion. On the other hand it is necessary to compare many curves during the production run, to determine the limits within which the response is likely to occur, or summarize the level at which production is running.

The control charts shown in Figure 4 do just this but they are not in a form usually understood in communication laboratories.

One method of summarizing many receivers on a single sheet is to draw an up-

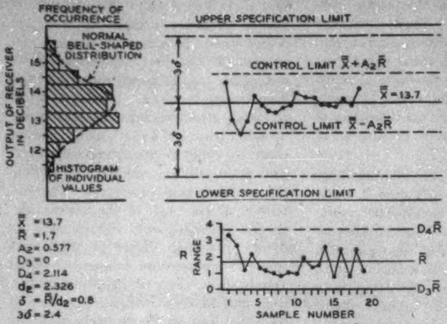

Figure 3 (above). Histogram and control chart of receiver response at 400 cycles per second

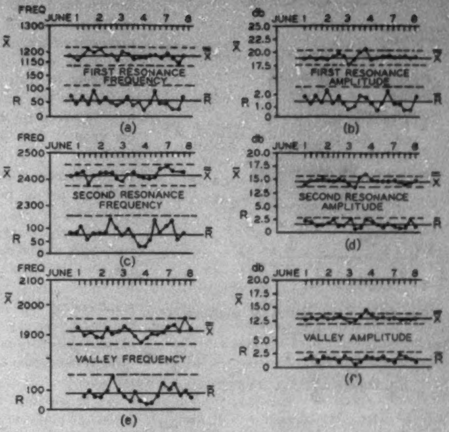
Figure 4 (right). Control charts for receiver at higher frequencies

$\bar{X}$ = average $\bar{\bar{X}}$ = grand average
R = range $\bar{R}$ = average range



per and lower curve representing the maximum and minimum response. Another is to draw an average curve and specify tolerance limits from it at each frequency. It is more effective to use the data presented in the form of control charts as in Figure 4. The average values and the standard deviations (σ) for all characteristics charted in Figures 3 and 4 obtained by methods previously indicated are shown in Table I.

A graph (Figure 5) can then be prepared showing the average values and the 3σ limits of amplitude and of frequency at resonance for individual receiver response curve. The 3σ limits are the limits within which we would expect 99.7 per cent of the response curves to lie at the four indicated frequencies. The advantages of this presentation are that the variations likely to occur in resonant peaks and cutoff frequencies are better defined than by the upper and lower limit curve.

Table I. Receiver Characteristics Obtained from Control Charts of Figure 3

Characteristics	Grand Average $\bar{X}$	Average Range $\bar{R}$	Standard Deviation from $\sigma=\frac{\bar{R}}{d_2}$
Amplitude at 400 cycles per second (decibels)	13.7	1.7	0.73
First resonant frequency, cycles per second	1188.	56.	24.
Amplitude at first resonance, decibels	18.9	1.4	0.60
Frequency of valley between first and second resonance, cycles per second	2013.	94.	40.
Amplitude at valley, decibels	12.7	1.3	0.56
Frequency of second resonance, cycles per second	2420.	78.	33.
Amplitude at second resonance, decibels	14.6	1.4	0.60

Specification

The methods of statistical quality control are helpful in controlling the manufacture of a transducer and in representing its performance. A similar situation exists in writing the specification. Two forms of specification are used in discussing the characteristics of transducers. The first type of specification is form "A" in Table II wherein the average output and tolerance are specified for each frequency.

Another method of specifying the response characteristics of a receiver is form "B" in Table II. In this system the absolute value of the frequency response is listed at a single frequency and the frequency response curve is specified as the deviation from the 400 cycles per second response, in this instance. The proponents of form "A" claim that they are specifying the absolute levels more closely. The proponents of form "B" claim that they are specifying a more uniform frequency response. Form "B" may properly be used only within regions where the response is controlled by a single set of causes. Such a condition exists within the low-frequency region of the receiver described in this paper, but does not extend from the low-frequency region to the high-frequency region. The three top histograms of Figure 6 show the distribution of the outputs of a group of receivers at 200, 400 and 2,500 cycles per second above a single reference level. This is a form in which data might be submitted to indicate compliance with form "A" of the specification. If these same receivers had been manufactured for a customer using the specification in form "B", the lower histogram of Figure 6 would be submitted in support of the receivers meeting the specification. The 400 cycles per second condition is identical. The 200 cycles per second response shows that at this frequency the response is much like that at 400. The distribution is very narrow. The average value agrees with the specification but the distribution is narrower than the tolerance. The low-frequency response of the receivers is stiffness controlled. Both the 200 and 400 cycles per second response are controlled by the same system of causes. Here it seems legitimate to use form "B" of the specification.

At 2,500 cycles per second these same

Table II. Specification of Frequency Response

Form A		Form B	
Receiver Output under Standard Conditions, Decibels	Frequency, Cycles Per Second	Receiver Output under Standard Conditions, Decibels	Receiver Frequency Response Based on 400 Cycles Per Second Response as 0, Decibels
12 ±2.5	200		−0.5 ±2
12.5 ±2.5	400	12.5 ±2.5	0
13.5 ±2.5	600		+1.0 ±2
16.0 ±2	800		+3.5 ±2
18.0 ±2.5	1,000		+5.5 ±2
19.0 ±2.5	1,200		+6.5 ±2

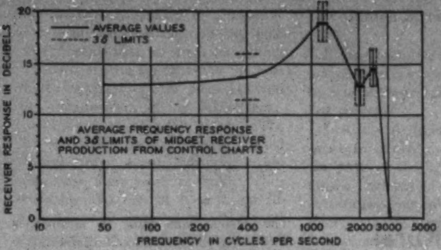


Figure 5. Curve showing 3σ (three sigma) limits of response of miniature receivers in production (data from Table I)

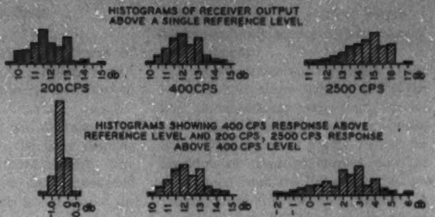

Figure 6. Histograms of receiver response at 200, 400, and 2,500 cycles per second

receivers now exhibit a wider range of variation than in the upper histogram. The 2,500 cycles per second response is not closely related to the 400-cycle response. It is actually a function of the Helmholtz resonator parameters, which are individually controlled. Hence this is a narrower distribution when viewed from a fixed reference level, as is done in the upper histogram. Specification form "A" appears preferable here.

At times the application of a transducer or the point of view of the specification writer has dictated the form in which the specification is written. In cases where the absolute value of the sound pressure output of the receiver must be controlled, the specification is written in form "A." In instances where the smoothness of the response is of primary concern, form "B" is used. When the manufacturer of the device writes the specification he should make it conform to the performance of the unit. Under such conditions it is possible that a portion of the specification such as the low-frequency response of the receiver will be written in form "B," and the remainder of the specification which covers the high-frequency response in form "A."

In all instances it is necessary to understand thoroughly the type of performance which is to be expected from the device and the reasons for the type of performance before plotting any control charts, or before choosing the form of the specification.

Conclusion

Although this paper has been confined to the discussion of control chart technique for simplifying the manufacture of a receiver to a desired sensitivity, uniformity, and quality, the principles involved are not restricted. We have kept similar plots and applied control chart technique to the control of manufacture of microphones, phonograph pickups, and to curves of the frequency response of amplifiers. There appears to be no reason why any series of characteristics mechanical, electrical, or physical could not be similarly treated, and the desired control obtained. Similarly it would appear possible to analyze and present composite pictures of response graphs whenever homogeneous data and operation under controlled conditions exists.

NONMEMBER AIEE

As rural electrification expanded, it became apparent that the requirements for supplying good service to consumers served by the long lines with low-load density, were different than for consumers in more thickly settled regions, for which equipment and operating practices had been developed. In rural territory the distribution system forms the main conducting network linking different areas, but in urban territory there are many other parallel conducting paths such as gas and water pipes, cables, and rails, which constitute extensive grounded networks. On these rural systems there are fewer consumers per mile, grounds are higher in resistance, lines are longer and higher in impedance. The lightning exposure is more severe, and the distances to be traveled in maintenance work are much greater. For these reasons, the construction and equipment typical of rural distribution systems became somewhat different from those typical of urban systems.

Several studies [1,2,3,4] have been made to investigate the effects of lightning on distribution systems, but none on a typical 7,200-volt multigrounded rural system. Hence, in 1944 the General Electric Company and the Central Electric Cooperative, Inc., at Parkers Landing, Pa., started a joint investigation aimed at the improvement of rural service.

The field work was in the charge of an engineer from the lightning arrester and distribution cutout division of the General Electric Company during the summers of 1944 to 1947 inclusive. The Central Electric Cooperative, Inc., made the investigation possible through the support of its board of directors and personnel.

Objectives

The principal objectives of the field investigation were:

1. To determine the nature and frequency of occurrence of lightning surges.
2. To measure the number, magnitude, and duration of 60-cycle transient currents.
3. To determine the short circuit and recovery voltage characteristics of the system.
4. To study each outage and to minimize consumer outages by improving the overcurrent protective system.
5. To learn the problems of operating a rural system from the viewpoint of the operating personnel so that practical improvements can be made.

The System Studied

The Central Electric Cooperative, Inc., serves an area of about 40 by 60 miles bordering on the Allegheny River in northwestern Pennsylvania, Figure 1. Isokeraunic maps predict 36 to 48 thunderstorm-days per year in this region. The system was built in accordance with Rural Electrification Administration (REA) Specifications. The first part of the system was energized in 1938, and the last large section was energized in 1941. It has continued to grow as more consumers were connected to existing lines and by adding numerous small extensions to the lines.

In 1947 there were 5,800 consumers supplied from 3,410 distribution transformers on 1,100 miles of line. The four principal feeders numbered 1, 50, 100, and 200 start as 3-phase lines from the substation and branch into single-phase lines. The substation contains two 900-kva banks of transformers rated 25-7.2/12.47 (Y-grounded) kv. Practically all apparatus on the system was made by one manufacturer.

All data are based on the equipment in service for the period of recording the data which was not constant during the four years of the study, due to system growth and changes made in the investigation as it progressed. Hence, data are reported in terms of installation-years; that is, lightning-arrester-years or oscillograph-years, and so forth.

Figure 1 also shows the location of the equipment used in the investigation. In 1944, 1,307 Hi-stroke expulsion lightning arresters, which had just been developed, were installed on feeder number 1 to study their performance. Each of them was equipped with surge crest ammeter links, hereafter referred to as links, to measure discharge current. Almost all the lightning surge measurements were made on this feeder.

Locations with Complete Magnetic Link Coverage

Magnetic links[5] were used extensively because they provide inexpensive, if approximate, measurement of surge current magnitude and polarity. Links were installed on each conductor connected to the group of distribution transformers where the cathode-ray oscillographs were and at other locations in their vicinity for the purpose of seeing how surge currents

---

Paper 49-110, recommended by the AIEE protective devices committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted November 15, 1948; made available for printing December 24, 1948.

D. D. MacCarthy and D. A. Stann are with the General Electric Company, Pittsfield, Mass.; D. R. Edge is with the Graybar Electric Company, Chicago, Ill.; and W. C. McKinley is with the Central Electric Cooperative, Inc., Parkers Landing, Pa.

The authors wish to acknowledge the valuable contributions made to this field investigation by the personnel of the Central Electric Cooperative, Inc. and by the following members of the General Electric Company: J. W. Kalb and W. H. Eason of the lightning arrester engineering division, and J. H. Leh of the Pittsburgh office engineering division.

were distributed, similar to Figure 2. Links were also installed on the pole ground wires; that is, wires connecting the system neutral conductor to the pole ground at many of the poles between these transformers giving rather complete coverage of 8.5 miles of line. The links at these locations were tested promptly after every lightning storm during the four years of study, thus minimizing the loss of records due to superposition of surges. All current determinations at these locations were made by calibrating the links individually to obtain greater accuracy than is possible if the magnetic characteristics are assumed to meet an average curve. A sensitive laboratory-type galvanometer was used to measure the residual magnetism.

With this technique and with the link spacings used, measurements were possible over a range of approximately 100 to 30,000 crest amperes.

By studying the polarity and magnitudes of the records, it was usually possible to determine how the surge arrived at a transformer location. By correlating the link records from adjacent locations, it was often possible to determine how the surge reached the part of the system covered by these link installations.

The Church Stroke Case

A very complete set of records was obtained from a stroke to a church served by one of the transformers with complete link coverage.

In this case, there was abundant evidence in addition to the links defining the path of the lightning current. The stroke terminated on an ungrounded ornamental zinc sphere at the top of the church steeple as shown by holes freshly burned in it. It jumped from the rod supporting the ornament to the steeple and shattered a 4 inch by 6 inch by 18 foot wooden rafter. It left the steeple, passed through the main roof of the church scattering more slate shingles, and terminated on the Romex wiring above the ceiling. On the ground floor, a 15-ampere plug fuse was shattered and an open knife switch was arced over. The filaments in some of the church lights were vaporized. In the basement, a 60-ampere cartridge fuse was blown. The current passing into the 150-ohm service ground is unknown. The currents measured in the secondary wires at the transformer traveled through the 3-wire Alnico magnet watthour meter which was tested and was not damaged or decalibrated. These currents reached the transformer over the 180-foot length of 3-wire secondary service without causing further damage.

The transformer was connected to the end of a short, single-phase branch of the line. A cathode-ray oscillograph was installed there in addition to the magnetic links. The arrows in Figure 2 show the direction of negative current flow, as determined from the links, and the adjacent figures give the crest currents. A total current of 31,700 crest amperes arrived at the transformer over the secondary service phase and neutral wires. This current, divided between several wires, 5,600 amperes went to ground via the ground and guy wires at the pole; 6,700 amperes went out on the system phase wire and were measured by magnetic links on the lightning arrester ground wire and by others on the system phase wire; 19,500 crest amperes went out on the system neutral wire. The sum of the current leaving the transformer is 31,800 crest amperes which is in unusually good agreement with 31,700 amperes, the total current measured in the secondary service wires. The cathode-ray oscillogram obtained is discussed under Cathode-Ray Oscillograms.

The transformer and pole wires were examined with great care, and the transformer was returned to the factory for test and detailed examination. No evidence of damage or flashover was found; hence, the currents of 8,200 and 11,000 amperes in the secondary phase wires passed through the transformer secondary windings to the grounded neutral.

The inductance of these windings is low for currents flowing in the same direction in the phase wires because the ampere-turns in the two halves of the secondary are opposed. The magnetic link records definitely show that a negative surge arrived at the transformer over the secondary service wires and then left

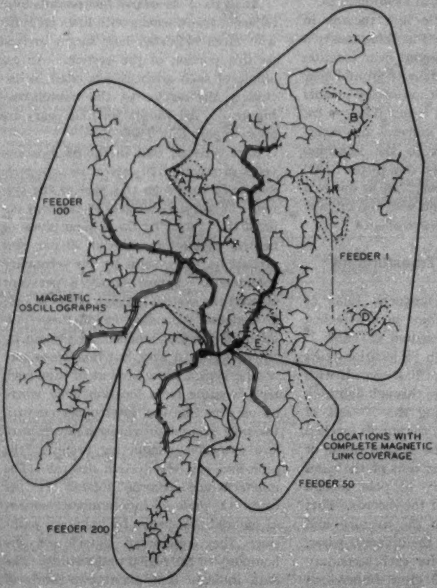

Figure 1. System map for Central Electric Cooperative, Inc.

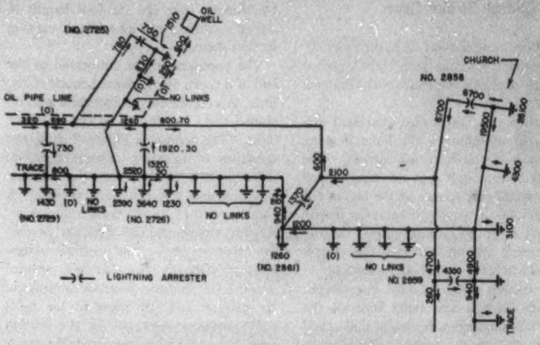

Figure 3. Distribution of the lightning surge currents for the church stroke case

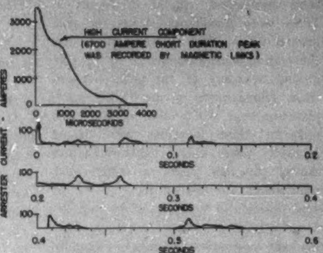

Figure 4. Replot of oscillogram showing long duration lightning arrester discharge resulting from stroke to church steeple

the transformer by every other connected wire.

Other records obtained in the vicinity of the church during the same storm illustrate the correlation often found between magnetic link records at adjacent transformers having links on each conductor connected to the transformer. Figure 3 is a diagram of the system phase and neutral wires in the vicinity of the church, which is at the right. The arrows near the lines give the direction of negative current flow and the adjacent figures, the magnitude. In cases where surge reversal was indicated, this value is given as a percentage following the crest magnitude. The currents in the indicated grounds are the algebraic sum of the currents in the guys, pole ground, and secondary phase, and neutral wires. In Figure 3, the 19,500 amperes leaving the church by the system neutral accounts for the negative currents measured to ground at transformer locations 2859 and 2861. The neutral current cannot be accounted for quantitatively because links were not installed on the ground wires at all of the intervening poles. However, the 6,700-ampere current leaving the church by the system phase wire shows up as 4,700 amperes at location 2859 and 2,100 amperes at location 2861, giving a sum of 6,800 amperes. The incoming and outgoing currents at both location 2859 and 2861 are in good balance. A current of 600 amperes left location 2861 by the system phase wire. This is considered to be the origin of the 560-ampere current of the same polarity recorded as a 70 per cent reversal of the 800 amperes in the system phase wire at location 2726 and as a 30 per cent reversal of the 1,920-ampere lightning arrester discharge current at this location. The surges from the church, indicated as reversals at location 2726, necessarily arrived after the larger surge currents had been recorded. Thus, one negative stroke entering the system via the secondary service wires at the church caused four lightning arresters to discharge over a total length of 1.25 miles of system. These lightning arrester discharges were 6,700 amperes positive at the church, and negative discharges of 4,300 amperes at location 2859, 1,370 amperes at location 2861, and 580 amperes at location 2726.

The other magnetic link records in Figure 3 are interpreted as being due to a negative stroke to ground near location 2726 and a positive stroke to ground near location 2729. The origin of the records at location 2725 is not clear. The system phase current of 780 amperes also measured as 750 amperes in the lightning arrester may have been due to the 1,260 amperes leaving location 2726, or due to a surge in the pole ground wire and oil pipe line at location 2725.

Surge Currents at Transformers

Results from the magnetic links at transformers where they were attached to every wire are presented in Table I. The data are based on 88 location-years and include 120 sets of link records with records of 86 discharges through lightning arresters. Disregarding the 20 sets of indeterminate records, the surges reached the transformer by the system phase or neutral wires in 64 per cent of the cases and by the secondary or pole ground wires in 36 per cent of the records. Part C of the table gives the average and maximum currents in the different wires. The average current for each secondary wire was about 1,000 crest amperes as was the average in the system phase wire. The average currents measured were 1,270 amperes in the system neutral wire, 1,670 amperes through the lightning arrester, and 2,240 amperes through the pole ground wire. The large number of records in all wires is a result of the lightning arrester providing a path between the system phase wire and the group of wires consisting of the system neutral, pole ground, and secondary wires.

How Surges Reach the System

Analysis of the sets of link records from adjacent transformers with links on every wire often indicated how surges arrived on this portion of the system. An example of such analysis was cited in discussing the stroke to the church, see Figure 3. All results for four years are given in part D of Table I.

It is believed that in the 88 location-years of record, 120 sets of records were due to 72 surges on this part of the system. Of these 72 surges, 29 per cent entered the system by the system phase or neutral conductors. About 29 per cent arrived on the system by the secondary conductors. Approximately 8 per cent entered the system through both the pole ground and secondary conductors. Another 12 per cent reached the system by the pole ground wire, but this figure may not be typical since six out of nine such records came from location 2725 where an oil pipe line was interconnected with the pole ground providing a junction of two extensive conducting systems, the pipe line and the system neutral. The indeterminate records totaled 21 per cent. Of these 15 indeterminate surges, 11 entered the system by unknown paths since they originated outside of the boundary of the region under study. The data indicate that about two-thirds of the surges may enter a rural system by the secondary or ground wires. This is due to the close proximity between the secondary circuits and exposed objects such as wired buildings or trees near the buildings, and the connection between the secondaries, out-buildings, and water systems. This result had not been anticipated.

Long Duration Lightning Surges

Cathode-ray oscillographs were used to measure long duration surges at a small group of distribution transformers on feeder number 1. Table II gives the characteristics necessary to understand the data. Each oscillograph had two cathode-ray tubes connected to shunts containing Thyrite to extend the measurable range. At the onset of a storm, the operator energized each oscillograph. The cathode beam initiated automatically in 20 to 50 microseconds when the transient current measured by either tube exceeded a value that depended somewhat on the wave shape. Six of these cathode-ray oscillographs were in operation during 1944. They were connected to measure both arrester and transformer primary currents. The impulse currents in the transformer primaries were measured to determine if they were capable of blowing transformer fuses. In 1945 a seventh oscillograph was installed, and four of them were changed to use both tubes to measure lightning arrester current over an extended range instead of measuring surge currents in the transformer primary winding. The oscillographs were operated in 1944 and 1945 but were then discontinued to enable the field engineer to concentrate on other aspects of the investigation. Magnetic links were installed on all wires connected to the distribution transformers at the oscillograph installations, see Figure 2. These links measured short duration surges that the oscillographs could not register.

During nine oscillograph-years of record, no lightning currents of significance were measured through the transformer primary. The lightning arrester was connected on the line side of the fuse. No transformer fuses were blown due to lightning at these locations.

Figure 5. Oscillogram of long duration discharge obtained at church

Table III summarizes the results from the 17 cathode-ray oscillograms of lightning arrester current. During the 13 oscillograph-years of record, the lightning arresters discharged 22 times as shown by oscillograms, magnetic link records, and scars on the electrodes of the expulsion lightning arrester series gaps. The electrodes were changed after each scar to relate the nature of the burns and the discharge currents. Five of the 22 discharges were too short in duration for the oscillographs to record. The crest current and total duration from beginning to the end of the discharge are given in Table III together with the crest current measured by the magnetic links.

Figure 4 is a replot of the oscillogram resulting from the stroke to the church. The record occupies 27 inches of film and the deflections are small making it impractical to reproduce the entire oscillogram; Figure 5 shows the first part of it. The peak current of 6,700 amperes recorded by the links was too short in duration for the oscillograph to record. The oscillogram shows an initial current peak of 3,500 amperes that reached a virtual zero in about 3,000 microseconds. There

were six subsequent long duration discharges in the stroke, none of them exceeding 90-amperes crest. The last of these discharges ceased after 0.55 second, which is the total duration given in the table. The individual discharges lasted from 0.017 to 0.071 second. The current was less than 10 crest amperes and may have been zero for a total of 0.3 second during the 0.55 second total duration of the discharge. This surge did not cause the primary fuse to blow, did not damage the Hi-stroke lightning arrester, nor was follow current established. However, follow current may have been established in one of the other lightning arresters which discharged simultaneously. Calculations show that this discharge was sufficient to blow primary fuses rated 30 amperes or less that might have been in its path. No current was recorded by the element connected to measure transformer primary current. This stroke produced the most severe record obtained. This oscillogram was preceded by another on a different time axis on the same film showing a positive current of 140 amperes, 500 microsecond duration through the lightning arrester, see Figure 5. This 140-ampere discharge was due to a negative lightning stroke which occurred at least 12 seconds before the steeple was hit and splintered a tree across the road from the church.

The second highest oscillographic record showed a crest current of 2,000 amperes and 5-milliseconds duration. It is reproduced in Figure 6. There was no follow current or transformer magnetizing transient. The set of link records indicates a negative surge arriving on the system phase wire recorded as 6,500 amperes in the lightning arrester and going out on the system neutral, pole ground, and secondary wires. The sum of the outgoing currents recorded is 5,700 amperes crest.

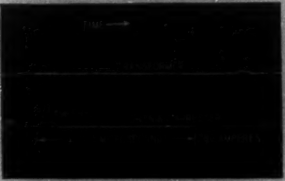

Figure 8. Cathode-ray oscillogram showing lightning arrester follow current

The 17-ampere 0.061-second oscillogram is reproduced in Figure 7 to illustrate a low current of long duration. Both traces show lightning arrester discharge current, the upper being from the oscillograph tube giving one millimeter deflection for 15 amperes, the lower from the other tube giving one millimeter for 100 amperes. This record was obtained at location 2725 during the same storm that produced the record at the church.

Many of the 17 oscillograms listed in Table III are not severe enough to be of importance. The first nine are traces merely showing long duration discharges through the lightning arresters. All of these traces are much less severe than a half cycle of follow current at these locations which would be recorded as 200 to 300 amperes crest and 8.3 milliseconds. The average current was usually much less than the crest. The current was apparently zero for more than 0.30 second during the 3,500-ampere record and for 0.16 second during the 40-ampere, 0.66-second record. The 2,000 and 3,500-ampere oscillograms listed last in Table III, Figures 4 and 6, are far more severe than the others. These oscillograms show that lightning arresters on rural distribution systems discharge long duration surges that occasionally, as in the case of the stroke to the church, may be of great severity. The probability of long duration discharges through lightning arresters is much greater on rural than on urban distribution systems because of the greater exposure, lower density of connected transformers, and absence of extensive systems of grounded conductors.

Only one cathode-ray oscillogram of follow current through arresters was obtained, see Figure 8. Since it showed no long duration lightning discharges, it was excluded from Table III. A second half cycle of follow current occurred five half cycles after the first; it was accompanied by a transformer magnetizing current transient shown in the upper trace. The link records of 300 amperes 100 per cent reversal in the lightning arrester and primary phase wires are believed to be the result of the follow current. The set of link records indicate that a negative surge totaling 1,150 amperes arrived via the secondary phase wires and went out on the system neutral and phase wires. It is surprising that 60-cycle follow current was started only once as shown by the oscillograms obtained from 13 lightning-arrester-years of experience since follow current was started readily at all of the oscillograph locations when each oscillograph was tested with a portable impulse generator to insure that it was in working order. The lack of follow currents is at least partly the result of several lightning arresters discharging simultaneously due to one surge on the system which could start follow current through only one of the lightning arresters. In other cases, the line may have been de-energized as by the operation of a recloser, or the lightning surges may have occurred near the zero point of power voltage wave.

Table III. Summary of the 17 Long Duration Lightning Strokes Obtained in 1944 and 1945

Discharges Through Representative Groups of Lightning Arresters

Data from the links at transformers with links on every wire indicated that one surge frequently caused several lightning arresters to discharge and gave information on the number of times individual lightning arresters discharged. More information was desired, so in 1946 five widely separated groups of about 40 lightning arresters each were selected for a more detailed study, see areas A to E inclusive in Figure 1. Links at these transformer locations were installed on only the lightning arrester lead. The links in these five groups were checked 18 times between April 8 and November 25, 1946 to minimize the records lost by superposition. The average interval between inspections was 11 days and the maximum was 20 days. Currents below 5,000 amperes crest were determined from curves based on average link characteristics; larger currents were determined by calibration of the individual links.

Number of Lightning Arresters Discharging Due to One Surge

Link data from each of the five lightning arrester groups were spotted on system maps, see Figure 9. Many sets of records occurred in which every adjacent lightning arrester had discharged currents of the same polarity. These sets of discharge currents were interpreted as resulting from one surge on the system. The currents usually decreased at each successive lightning arrester away from the one with the highest current assumed to be nearest the stroke terminus. In a few cases, the polarity or magnitude of the currents indicated that one set of records was due to two separate surges.

This is illustrated by the records in the two lefthand sets of records in Figure 9. Each dot in this figure represents a lightning arrester; the polarity, crest current, and per cent reversal of the lightning arrester current are adjacent to the dots. The upper set of records was interpreted as five lightning arresters discharged by a negative surge resulting from a stroke nearest the lightning arrester which discharged 17,500 amperes, 2 per cent reversal. The trace at the extreme upper left was excluded because it was of positive polarity. On the basis of current magnitude, the middle set of records was interpreted as four lightning arresters discharging negative current resulting from another stroke. The set of records at the lower right is separated from the middle set on the basis of current magnitude and because one lightning arrester between the two sets did not discharge. This set of eight negative records, including traces, indicates eight lightning arresters discharged by one surge and is the maximum number found in these groups.

All data analyzed in this way are summarized in Table IV. The data are based on 293 lightning-arrester-years of experience. The 318 lightning-arrester discharges recorded are interpreted as resulting from 185 surges on the system or an average of 1.72 lightning arrester discharges for each surge. The number of lightning arresters discharging due to one surge ranged from one lightning arrester for 63 per cent of the surges; two lightning arresters for 19 per cent of the surges; on up to eight lightning arresters for one out of 185 surges. This surge caused discharges through lightning arresters on 1.8 miles of line.

In one case not included in these five groups, discharges were recorded through all 13 lightning arresters on three miles of line within a 1-mile radius of the lightning stroke terminus. The expulsion lightning arrester nearest the stroke burst due to the heavy surge current which exceeded 30,000 amperes, the upper measurable limit of the links. The currents were all of the same polarity and diminished in each successive lightning arrester away from the stroke terminus. These records show that surges may travel over long lengths of rural line and frequently cause more than one arrester to discharge.

Number of Times Individual Lightning Arresters Discharged

Table V summarizes the number of discharges per year for each arrester in the five groups, A to E, and for the lightning arresters at transformers with links on every conductor. Not all discharges were recorded since several discharges from multiple lightning strokes or from superposition of separate discharges in the interval between inspection contribute only one record. Based on 293 lightning-arrester-years, the lightning-arresters average 1.09 discharge per year as recorded by links; 32 per cent of the lightning arresters did not discharge;

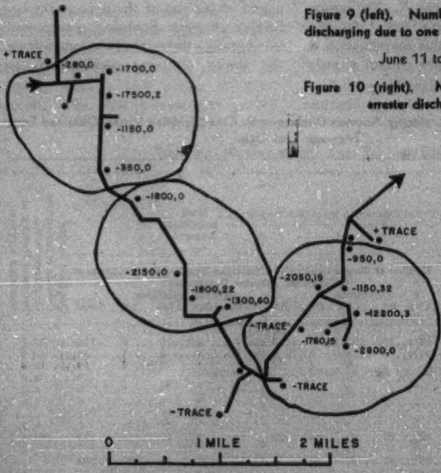

Figure 9 (left). Number of lightning arresters discharging due to one surge (Part of Group C)

June 11 to 28, 1946

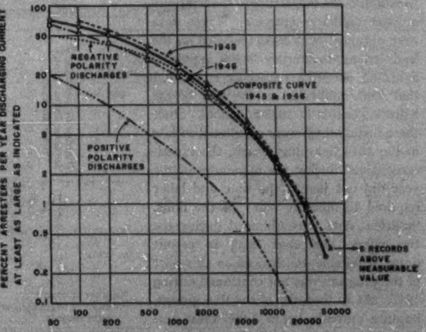

Figure 10 (right). Magnitude of lightning arrester discharge currents

40 per cent discharged once; and two lightning-arresters discharged at least four times during one year.

The variability in number of lightning arrester discharges is interesting. The 44 lightning arresters in group C averaged 1.5 discharge records per year, while the 43 lightning arresters in group A about 15 miles away averaged 0.67 during the same year.

Knowing the number of lightning arresters involved and the total discharges recorded, the law of independent trials can be used to calculate the number of lightning arresters expected to operate exactly once, twice, and so forth. This was done for the records from the 205 lightning arresters in groups A to E with the following results:

Records Per Lightning Arrester Per Year—Number, N	0	1	2	3	4	5
Calculated—Lightning arresters with exactly "N" records, per cent	32.2	36.6	20.4	7.5	2.1	0.6
Actual—Lightning arresters with exactly "N" records, per cent	29.3	39.5	21.0	9.3	1.0	0.0

The actual results show a trend toward fewer lightning arresters with no records and fewer with a large number of records than are calculated. This trend is consistent with the tendency for one surge to produce a record in more than one adjacent lightning arrester; that is, the average of 1.7 lightning arrester discharges per surge cited previously.

Impulse Currents Discharged by Expulsion Lightning Arresters

Link data obtained from the five groups and other locations on feeder number 1 selected for frequent inspection were used to estimate the frequency of lightning arrester discharges on this rural system. A larger amount of data were necessary to establish the magnitude of the lightning arrester discharge currents. These data were obtained from links installed on the leads of approximately 1,300 expulsion lightning arresters on feeder number 1 that were calibrated at the end of the lightning season in 1945 and 1946. Since these installations were completed so late in the 1944 lightning season, the experience gained during the remainder of the year did not justify the time and labor required to measure many of the links. Sufficient data were obtained during the two years, 1945 and 1946, to permit drawing reliable conclusions so this part of the program was not continued during 1947. As in the case of the five groups, impulse currents below 5,000 crest amperes were determined from average characteristic curves; larger currents were determined by calibration of the individual links with a sensitive laboratory galvanometer.

The magnitude of the impulse current obtained in this way is illustrated in Figure 10. The data for 1945 and 1946 are in good agreement. The composite curve represents the 1,685 impulse current records obtained during both years. It indicates 67.3 per cent of all the expulsion lightning arresters discharged at least once per year. This corroborates similar data obtained from the selected groups, see Table V. Only 0.36 per cent or six of the 1,685 records exceeded 30,000 crest amperes. Other curves based on 1,685 records separate the lightning arrester discharges according to polarity. Approximately three-quarters of the lightning arrester discharges were negative in polarity; this preponderance became more pronounced with increasing discharge currents. No positive arrester discharges greater than 15,000 crest amperes were measured. There were 26 negative discharges of 15,000 crest amperes or more.

A comparison of the results obtained by McEachron and McMorris[3] on rural systems with those from this investigation are summarized in Table VI. The results are in close agreement except for the lower currents. In this investigation a higher proportion of low current records was obtained because of the higher sensitivity of the instruments used.

Lightning Arrester Follow Currents

Automatic magnetic oscillographs recorded abnormal 60-cycle power currents such as lightning arrester follow currents, fault currents, and load inrush currents.

A magnetic oscillograph was installed on feeder number 1 approximately two miles from the substation during 1945, 1946, and 1947. The symmetrical short circuit current decreases with the distance from the substation. It was 700 rms amperes at the oscillograph and about 31 amperes at the extremity of the line. Any currents within this range in the phase conductors or in the neutral initiated the oscillograph within one half cycle. This oscillograph recorded follow currents through all expulsion arresters on feeder number 1 except 26 between the oscillograph and the substation.

Another magnetic oscillograph was located near the beginning of feeder 200 during 1946 and 1947. This oscillograph added data to the overcurrent investigation but not to the lightning study since the majority of the lightning arresters on this feeder were of the valve type and limited the follow current to values incapable of initiating the oscillographs.

The vibrators of each oscillograph measured the currents in phases A, B, C; the neutral current; and the voltages of phases A and C to ground. A short circuit through a 2-ampere fuse was placed at the end of the lines at the beginning of each lightning season and occasionally thereafter to demonstrate the ability of these oscillographs to

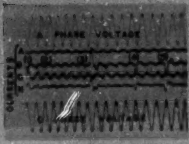

Figure 11. Magnetic oscillogram of follow currents resulting from multiple lightning stroke

initiate automatically due to the lowest fault current on the feeder.

Interpretation of Oscillograms

An interesting oscillogram resulting from a multiple stroke is reproduced in Figure 11 to illustrate the method of interpretation. Point 1 on this oscillogram indicates a lightning disturbance causing follow current through lightning arresters on B and C phases. The half cycle of follow current in each of these two phases was not recorded because of the time required to initiate the oscillograph. However the magnetizing transients are evidence that these lightning arresters discharged follow current. Point 2 shows lightning arrester follow current of a small magnitude in A phase lasting less than one half cycle. Half cycles of follow current in B phase are recorded at points 3, 4, and 5. The follow currents ranged from 50 crest amperes through the A phase lightning arrester at point 2 to 304 crest amperes through the B phase lightning arrester at point 3 presumably due to difference in timing angle. The duration of this multiple lightning stroke, which was taken as the time from first to the last half cycle of follow current inclusive, was 32 half cycles or 0.267 second. The time interval between the successive lightning arrester discharges was measured in half cycles between corresponding points at the beginning of each of the respective follow currents. For example, the time intervals between lightning arrester follow currents numbered 1 through 5 were 6, 11, 9, and 6 half cycles respectively.

Blowing of line fuses during a lightning storm with no corresponding record of fault current sufficient to blow the fuse was attributed to lightning.

Multiple Lightning Stroke Data

Oscillograms with intermittent half cycles of lightning arrester follow current, except where all follow currents occur simultaneously, are interpreted as due to multiple lightning strokes. By this definition, 22.5 per cent of the 1,481 follow current records obtained over a period of three years resulted from multiple lightning strokes, see Table VII.

Multiple stroke data were obtained by many investigators employing different measuring techniques. McEachron[6] obtained 184 crater lamp oscillograms showing follow current discharges through expulsion tubes on 138-kv lines; of these, 28 per cent were multiple. During another investigation conducted in the Pittsfield Lightning Observatory,[7] Hagenguth found that 37 per cent of the 619 lightning records obtained by means of a Boys camera were multiple in nature. Similarly the 65 Boys camera lightning records obtained during Schonland's Investigation[8] show that this percentage was 51. Stekolnikov and Valeev[9] used a Klydonograph with a fast moving film to show that 72 per cent of 25 records were due to multiple strokes.

All these different methods of recording multiple lightning strokes have limitations. Boys cameras may fail to record photographically weak lightning strokes. Electromagnetic oscillographs do not record strokes which fail to cause lightning arrester follow current, nor do they distinguish between successive surges occurring within the same half cycle. Klydonograph accuracy is limited by the film speed and the ability to interpret nearly superimposed Lichtenberg figures. All these instrument limitations tend to render too low a number of multiple stroke discharges.

Table VI. Comparison of Lightning Arrester Discharge Data

	McEachron and McMorris (Rural only)	Central Electric Cooperative, Inc. (Rural)
Number of lightning-arrester-years	1,709	2,503
Number of lightning arrester discharge records	909	1,685
Per cent lightning arresters discharging at least once per year	43.6	67.3
Per cent lightning arresters discharging per year currents greater than:		
1,000 amperes	28.9	25.0
5,000 amperes	7.3	6.0
15,000 amperes	1.75	1.4
Per cent of records that were of negative polarity	65.7	72 0

The maximum number of times follow current was started during this investigation due to one multiple stroke was 15. Analysis of 1,481 follow current oscillograms shows 22.5 per cent with follow current starting two or more times, 8.1 per cent three or more, 3.5 per cent four or more, and 1.9 per cent five or more.

All 333 multiple follow current oscillograms accumulated over a 3-year period were analyzed for total durations and the time intervals between separate lightning

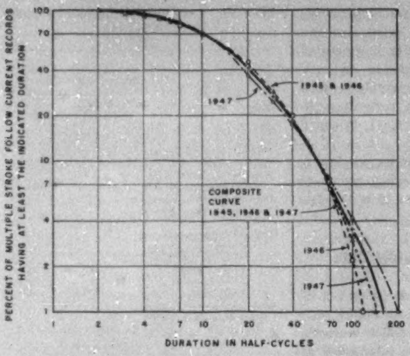

Figure 12 (above). Duration of multiple lightning strokes

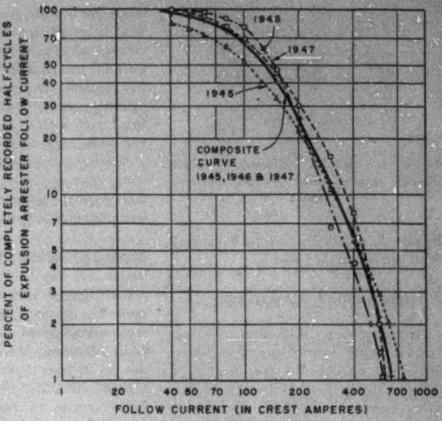

Figure 13 (right). Magnitude of lightning arrester follow currents

arrester follow currents. The total duration of these multiple follow currents is plotted in Figure 12 to show general trends. The yearly tendencies in multiple stroke duration were very consistent up to one second. Beyond this duration the number of oscillograms becomes progressively less; consequently, the curves show a greater divergence. The most probable, the average, and the maximum multiple stroke durations were 0.117, 0.19, and 1.83 seconds respectively. Similarly the most probable and the average time intervals indicated between individual discharges of multiple strokes were 0.084 and 0.17 second.

Expulsion Lightning Arrester Follow Currents

The 1,481 oscillograms with records of follow current covering 4,054 expulsion lightning-arrester-years of experience yielded a total of 2,479 half cycles of lightning arrester follow current. To compensate for the loss of oscillograms based on records of the short periods when oscillographs were inoperative, the total number of half cycles of follow current was estimated as 2,620. Using 2,620 half cycles of follow current, the average is 0.65 half cycle of follow current per lightning arrester per year, see Table VII. It must be remembered that the magnetic oscillographs recorded the number and magnitude of follow currents discharged through expulsion lightning arresters rather than the number of discharges or lightning strokes. These were precisely the data required to determine lightning arrester erosion life. Analysis of oscillograms shows that expulsion lightning arrester follow currents were interrupted at the first current zero in all but one per cent of the cases. Every such case resulted from a multiple stroke since there were several successive lightning arrester operations on the same oscillogram. These records are attributed to long duration discharges continuing for more than one half cycle or to several discharges which re-established follow current in successive half cycles.

To estimate the erosion life of lightning arresters, it is not only necessary to determine the number of half cycles of follow current discharged by lightning arresters but to measure the magnitude of the follow current. Because of the time required for initiation of the oscillograph, the crests of some half cycles of follow current were not recorded. The 693 crest values which were recorded are the basis of Figure 13. The average follow current magnitude was 182 crest amperes. Only 3.5 per cent of the follow currents were greater than 500 crest amperes. A probability curve drawn from these same data shows that the most probable follow current magnitude was 105 crest amperes. These figures apply only to this system.

A study was made to determine whether locations with high available short circuit current had a greater tendency to establish follow current. No correlation was found.

Single and multiple lightning arrester operations contributed a total of 1,481 follow current oscillograms with an average of 1.39 half cycles of follow current per lightning stroke. Considering only the multiple follow current records, this average was three.

Insofar as the authors are aware, this is the first investigation of the actual follow current duty of expulsion lightning arresters on a distribution system. Only 33 of the 1,481 follow current oscillograms show that follow current initiated five or more times. Furthermore, the average lightning arrester discharged only 0.65 half cycle of follow current which averaged 182 crest amperes. All data indicate that erosion is no problem for these expulsion lightning arresters when applied within their ratings. The erosion effect of impulse currents is negligible in comparison with erosion due to follow currents.

Line Flashovers

An average of three expulsion lightning arresters per mile of feeder number 1 was effective in reducing the number of line flashovers. Over a period of three years, 1,481 follow current oscillograms were obtained. To compensate for the time the oscillograph was inoperative, this number was increased to 1,577. Each of these would probably have caused a line flashover had the line not been protected by the expulsion lightning arresters. In addition to this, there were 1,046 temporary faults, or 0.7 per mile, on the line that cleared themselves or were interrupted by one oil circuit breaker opening. Therefore, assuming feeder number 1 was completely unprotected by lightning arresters and the 1,046 temporary faults were line flashovers, there would have been a potential total of 2,623 line flash

Table VII. Expulsion Lightning Arrester Follow Current Data—Feeder Number 1

overs on this line in three years, or 1.8 per mile of line each year.

Results and Conclusions

1. About one-third of the lightning surges arrived at distribution transformers by the secondary or pole ground wires.

2. About two-thirds of the surges reached the system phase and neutral wires from the secondary wires or pole ground wires.

3. The average surge current was about 1,000 amperes in each of the secondary phase and neutral wires, 1,070 amperes in the system phase wire, 1,270 amperes in the system neutral, 1,670 amperes through the arrester, and 2,240 amperes in the pole ground. The larger surges usually involved currents in all wires.

4. Seventeen long duration discharges through lightning arresters were recorded by cathode-ray oscillographs. These measurements indicate an average of 1.3 discharges per lightning arrester per year, although these data are too limited to establish a rate of expectancy. An oscillogram having a duration of 0.55 second was obtained of a severe discharge from a stroke which occurred near the oscillograph location.

5. Simultaneous discharge of lightning arresters at adjacent locations often occurred as a result of a single lightning surge. One severe surge discharged all 13 lightning arresters on three miles of line within a one-mile radius.

6. Expulsion lightning arresters on this system carry follow current less often than they discharge surge current since sparkover near power voltage zero may not start follow current and since only one arrester carries follow current when there is simultaneous discharge of lightning arresters on the same phase.

7. The number of times per year a lightning arrester discharges varies greatly with the locality and lightning severity. The links showed that 40 per cent of the lightning arresters discharged once; 19 per cent twice; 6.5 per cent three times; and 2.7 per cent four or more times per year. The lightning arresters averaged 1.1 discharge per year.

8. On a yearly basis, 0.36 per cent of lightning arresters discharged currents exceeding 30,000 amperes, 50 per cent at least 200 amperes, and 67 per cent at least 100 amperes

9. At least 22.5 per cent of the lightning strokes were multiple. These multiple strokes had an average duration of 0.19 second and caused an average of three separated half cycles of follow current through the expulsion lightning arresters.

10. The erosion duty was not severe for the expulsion lightning arresters used on this rural system since they discharged an average of only 0.65 half cycle of follow current per year with an average of 182 crest amperes.

11. The use of an average of three expulsion lightning arresters per mile reduced the number of line flashovers from an estimated 1.8 to 0.7 per mile of line per year.

Discussion

A. M. Opsahl (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The authors state that in the church stroke case, there were currents of 8,200 and 11,000 amperes measured in the two outside wires of the secondary circuit or an unbalance of 2,800 amperes between the two windings. At the rate of change of current which can be expected in such lightning surges, how can it be explained that there was not sufficient voltage developed across the low- to high-voltage reactance of the transformer due to this 2,800 amperes unbalanced or uncompensated surge current to flash over the secondary bushing?

One conclusion of this investigation was that about one-third of the surges arrived at the transformers over the secondary wires. This is a high percentage. Was any record kept of secondary circuit disturbances such as bushing flashovers or trouble in the services? A few thousand amperes surge current over the secondary bushing will leave a mark which can be seen even though it cannot be classified as damage. Disturbances in dwellings due to lightning on the secondary circuits can occur and some might have been reported. There was considerable concern over a possible increase in secondary troubles when the interconnection of primary arrester ground lead and secondary neutral was up for code approval. No appreciable increase in secondary troubles was found.

The authors found that expulsion lightning arresters spaced three per mile reduced line flashovers from 1.8 to 0.7 per mile per year. What was the flashover of the insulation protected and what was the approximate span length in the area?

D. D. MacCarthy, D. A. Stann: Opsahl has raised an interesting question as to why the unbalanced currents measured in the secondary phase wires connected to the transformer at the church did not cause the secondary bushings to flash over. The same line of reasoning prompted us to make a very critical examination of this transformer immediately after the disturbance was reported.

When no evidence of flashover was detected in the field, the transformer was returned to the factory for disassembly and careful examination of the windings. There was no evidence of any flashover or other damage. There are two alternative explanations.

First, the current unbalance of 2,800 amperes was determined as the difference between the 11,000 and 8,200 ampere currents in the secondary phase conductors. Since the magnetic link readings were accurate to within ±10 per cent and the 2,800 amperes difference was small as compared to either phase conductor current, it is possible that the unbalanced current may have been appreciably less than 2,800 amperes; in which case, there would be insufficient current to cause bushing flashover.

Second, a simple calculation shows that the 2,800 ampere unbalance in discharge current could have occurred without resulting in a bushing flashover if it had a slow wave front. A reasonable value for the self-inductance of one 120-volt secondary winding is 500 microhenries, assuming the core does not carry flux due to the impulse current. This is consistent with the absence of current in the transformer primary in the cathode ray oscillogram of Figure 5. The flashover voltage of the secondary bushings is approximately 40-kv crest. Since this bushing did not flash over, the 2,800 ampere current flowing in the inductance of 500 microhenries could not have reached crest in less than 35 microseconds. Because the cathode-ray oscillograph did not record the front of the current, the time to crest current was less than the maximum initiating time of the oscillograph, which is 50 microseconds. With a time to crest current of 50 microseconds, the voltage on the secondary bushing would have been 28 kv, which is below the flashover value. Apparently, the unbalanced current at the transformer reached crest between the approximate values of 35 and 50 microseconds. Therefore bushing flashover would not be expected under these conditions.

Opsahl also has asked if records were kept of circuit disturbances. Evidence of damage was sought for correlation with the magnetic link records from transformers with links on each conductor. In some cases blown house fuses, damaged light bulbs, or struck trees in the vicinity of the house were found. On this system, the lightning arrester ground was always interconnected with the ground at the pole, the transformer tank, and the primary and secondary ground conductors. This interconnection may decrease the severity of the disturbances in the secondary circuit caused by surges originating on the secondary and would be expected to increase the number of small disturbances resulting from surges originating on the primary.

Information was requested on the line insulation to interpret the reduction in the number of line flashovers attributed to the expulsion lightning arresters. The line was built in accordance to REA specifications. On most of the system there was a ground at each pole with a ground wire brought up the pole and connected to the system neutral wire and extended within two inches of the pole top.

The primary phase conductors were carried on pin insulators that have a critical impulse sparkover voltage of 100 kv positive and 130 kv negative for 1.5 by 40 microsecond waves. The insulator pins were not connected to the ground wire. The pole-top gap between the primary phase conductor and the pole ground wire was about eight inches. It has a critical flashover value of approximately 160 kv positive and 185 kv negative for 1.5 by 40 microsecond waves. The pole span lengths were of the order of 350 to 400 feet.

Transmission Line Design and Performance Based on Direct Lightning Strokes

E. L. HARDER
FELLOW AIEE

J. M. CLAYTON
ASSOCIATE AIEE

IT IS well known that the insulation requirements of transmission lines are determined by lightning and switching transients rather than by the normal frequency voltage. For lines up to the highest voltages now in use, lightning is usually a principal factor. Consequently, a method for predetermining the design requirements to provide a desired immunity against lightning tripouts is essential.

A great deal of thought and effort has been devoted to developing such a method. Much painstaking work has been done in the collection of information regarding lightning currents to provide a fundamental basis for the estimates.

In this paper there is presented a method which has been in increasing use for a number of years for specific design calculations, and which is based on the stroke current probability data. This method now is extended into a complete set of estimating curves covering the full range of insulation levels, span lengths, and tower footings encountered on transmission lines. This is essentially a refinement and extension of the general curves given by Monteith.[1] However, it takes into account the improved knowledge of the lightning phenomenon obtained through field research and confirmed by actual line performance during the intervening years.

The previous curves were based on the stroke voltage which was considered to be constant irrespective of what line structure was hit. This required the assumption and use of a stroke surge impedance. In the present curves the stroke current is taken to be independent of the line structure hit so that the stroke surge impedance concept is not required and the method is tied more directly to measured currents. The latter representation is believed to be more nearly correct for reasons that will be outlined. In general the changes from the previous curves are not large, particularly for the lower tower footings of 20 ohms or less. There are some significant changes for higher tower footings encountered in certain territories and for the shorter spans used for lower-voltage wood-pole lines, such as 33 kv. These differences will be enumerated. The new general curves also include shorter span lengths than were included previously.

The new method of approach involving the treatment of the lightning stroke current as a constant fixed current rather than as a constant voltage back of a stroke surge impedance was introduced by G. D. McCann and C. F. Wagner,[2,3] several years ago and the quite extensive field data accummulated to that time indicated that this was a better representation and gave results which more strictly agreed with experience. The new method brought to bear on the problem the valuable field data which had been collected on stroke current and the accompanying theoretical approach enabled these data to be interpreted for comparative purposes on all forms of line design.

Mechanism of Stroke to Line. In all methods of estimating lightning performance the mechanism considered is as follows. The direct stroke theory being well established, it is known that in a region of average storm intensity of 30 storm days per year, the line will be hit by approximately 100 direct strokes per 100 miles per year on the average. Thus a shield wire must be used to receive these direct strokes and thereby shield the remaining conductors. This may be a ground wire which provides a suitable shielding angle or a top phase conductor equipped with protector tubes. The lightning current then is expected to take the path along the shield wire, down the tower or towers, and through the tower footing resistance to ground.

The entire tower top and connected ground wire rise to a high voltage principally because of the *IR* drop in the tower footing.

Neglecting coupling between the ground and phase wires, all this voltage would be impressed on the line insulation. Coupling elevates the phase wire voltages, so that the actual voltage impressed on the insulation is the tower-top voltage to ground times (one minus coupling).

It is evident that the tower lightning current required to cause flashover can be determined for any given insulation level, tower footing resistance, and coupling factor. The relation is:

$$\text{Tower current to cause flashover} = \frac{\text{insulation flashover voltage}}{\text{tower footing resistance} \times (\text{one minus coupling})}$$

The probability of line flashover is the same as the probability of tower currents equal to or greater than this value.

The problem is not as simple as outlined up to this point for a number of reasons. The insulation flashover voltage must be given for the wave shape of voltage to which it is exposed, which depends in turn on the wave shape of the stroke current and such factors as span length, tower footing, and so forth. Tower inductance is important as well as tower footing resistance when the latter is low (under 20 ohms). The coupling varies with corona which is a function of the voltage, spacings, and so forth. Finally, while the most extensive lightning data

---

Paper 49-111, recommended by the AIEE transmission and distribution committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted November 17, 1948; made available for printing December 27, 1948.

E. L. Harder is consulting transmission engineer and J. M. Clayton is central station engineer, Westinghouse Electric Corporation, East Pittsburgh, Pa.

available are tower crest current data, the tower currents resulting from given stroke currents vary with span length and to some extent with tower-footing resistance. Hence direct experimental tower current probability data can be used only for lines having the same order of span length and footing resistance as those on which the data were taken. For other lines some means of correction is necessary.

There also is the possibility of midspan flashover. The considerations are similar to those for tower flashover. The stroke current must be carried away by the ground wire and flashover will occur if the resulting voltage exceeds the air insulation strength from ground wire to phase conductors.

On many lines, midspan clearances required for mechanical reasons are such as to result in a negligible number of midspan flashovers, and for this reason, certain estimating methods consider tower flashovers only. However, for a general method intended to cover all cases, midspan flashovers must be included for in some cases they may be appreciable. It is the different treatment of these practical matters that has given rise to several distinct estimating methods.[4,5]

The authors recognize that the use of tower current data is the most direct and accurate approach to performance calculations of lines having about the same span length and midspan clearance as those on which the data were measured. However, to provide a general analysis applicable to the complete range of designs used in transmission practice, a more fundamental approach is necessary. This method is based on the stroke current, tower currents then being calculated for each different design. The stroke current is treated as independent of the terminating impedance which it strikes.

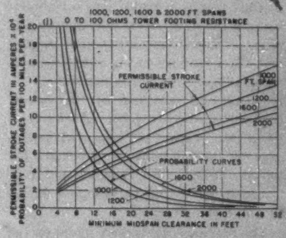
General Curves

It is evident from the foregoing discussion that the voltage to which the line



(j)

Figure 1. Curves for estimating line insulation and performance, based on 10-inch, $5^3/_4$-inch spaced suspension insulators, or equivalent, and an isoceraunic level of 30 storm days per year

The numerals on curves (a) to (h) indicate tower footing resistance, (i) and (j) length of span insulation is subjected depends on the following factors:

1. Stroke current magnitude and wave shape.
2. Tower footing resistance, and tower inductance.
3. Span length.
4. Line configuration including conductor spacings, height above ground, and so forth.

Using a typical line configuration and tower inductance and a 2-microsecond current wave, a general study has been made to determine the resulting voltages across the insulation at the tower and at midspan. The basis for the assumed parameters will be discussed later. This system was set up on the Anacom[8] (electric analog computer). The span length was varied from 200 to 2,000 feet and tower footing resistance from 5 to 100 ohms. This was done both for strokes entering at midspan and at tower. From the resulting potentials and wave shapes and the use of coupling factors taking into account corona, the stroke current required to cause flashover in each case was determined. These stroke currents are plotted in the general curves, Figure 1.

The probability of outage for a given case is simply the probability of stroke current in excess of that required to cause flashover. Figure 2 shows the stroke current probability curve used. The outage probabilities also are plotted in the general curves, Figure 1.

It will be noted that there are eight sets of probability curves, (a) to (h), giving outages for strokes to the tower for span lengths from 200 to 2,000 feet. Each set covers one span length giving the probability of outage as a function of number of insulators and the tower footing resistance for that particular span length. Where the insulation consists of wood or air in combination with porcelain the equivalent number of insulators should be determined as will be outlined subsequently. Each set of curves also gives the permissible stroke current as a function of the number of insulators and tower footing resistance. If more accurate stroke current probability data are available for the region being considered, these curves may be used.

Outage probabilities for midspan strokes are given in curves (i) and (j) of Figure 1 as a function of midspan clearance and span length only. This probability is substantially independent of tower footing resistance. For short spans the midspan flashovers would be slightly less than shown for any tower footings less than 100 ohms. However, for short spans the midspan flashovers shown are so low for practical spacings that this small reduction is unimportant.

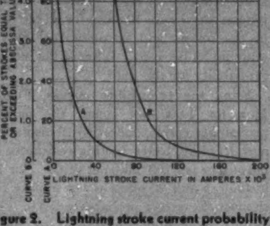


Figure 2. Lightning stroke current probability curve

Strokes per 100 miles of line per year for isoceraunic level of 30

Strokes to the line are assumed to be uniformly distributed along the line. It is further assumed that strokes within a quarter span length of the tower act as though at the tower, while strokes within a quarter span of the midspan act essentially like midspan strokes. Thus half the strokes are treated as strokes to tower and half are treated as strokes to midspan.

The probability curves, however, give the performance on the basis that all strokes are to tower, or all to midspan respectively. Thus it is necessary to average the two outage probabilities obtained from the tower and midspan curves respectively rather than add them. For a co-ordinated line, having equal probability of flashovers at the tower or at midspan either curve would give the complete outages for the entire line per hundred miles per year.

The probability curves are based on an isoceraunic level of 30 which denotes an average of thirty storm days per year. For other levels it is assumed that the outages will vary in direct proportion. An annual isoceraunic level map for United States is given in Figure 3.

The curves for estimating outages due to strokes to tower are based on a coupling factor corresponding to a 30-foot separation. For lower or higher separations the number of insulators should be corrected to allow for the corresponding change in coupling factor, the corrections being given in Figure 4. This correction is relatively unimportant for lines in the neighborhood of 132 kv, but becomes more important for the lower voltage lines such as 33 kv. The basis of this curve is given later.

On some lines the midspan clearance may be so high that even midspan strokes will cause flashover at the tower rather than at midspan. This can be determined by finding the permissible stroke current to tower and to midpsan. If the latter is more than twice the former, strokes to midspan can cause flashover at towers. In this case the outage probability for the line is the average of that corresponding to the permissible stroke current to tower and that corresponding to twice this stroke current. The resulting probability curve is given in Figure 5, the basis for which is stated in a subsequent section.

The general probability curves of tower outages have been plotted in terms of the number of $5^3/_4$-inch spaced insulators. Where other insulating media appear, they must be converted to equivalent insulators. The curves of Figure 6 provide a ready conversion from air or wood to equivalent number of insulators for estimating when more accurate data are not available. They are based on 100 kv per foot for wood and on the two microsecond time lag flashover values on $1^1/_2$—40 microsecond waves for air and for porcelain insulators. This wave shape is most representative of the tower-top potentials encountered. Conversions are discussed in greater detail later.

The probability curves are based on all

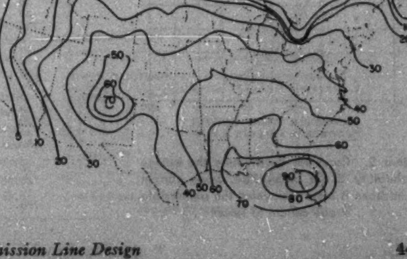

Figure 3. Annual isoceraunic map showing number of thunderstorm days per year

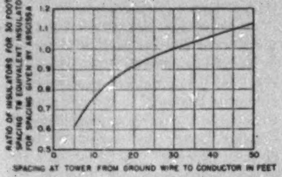

Figure 4. Correction factors for spacing at tower from ground wire to conductor

flashovers causing outages. All flashovers do not result in outages depending on the line insulation characteristics, and other factors. This reduction of outages is discussed in a later section.

Application of Curves. The use of the curves of Figure 1 in estimating the lightning performance of transmission lines will be illustrated by a few examples. The curves may be used for estimating the lightning performance of existing lines with various considered modifications. Or they may be used for estimating the insulation and midspan clearance required to obtain a desired lightning performance in the design of new lines. Because of the probabilities and assumptions involved the results should not be taken as rigorous. The chief value of the general curves lies in the facility provided for considering alternative designs on a comparative basis. A check of the estimating curves against a large amount of actual line experience does indicate quite good agreement.

Example I. A 220-kv steel-tower line, shielded by an overhead ground wire, located in a territory where the isoceraunic level is 50, has ten $5^3/_4$-inch spaced suspension insulators per string. The average span is 1,000 feet and the midspan clearance 24 feet. The tower footing resistances are 10 ohms for 20 per cent of the towers and 20 ohms for the remaining 80 per cent. What is the outage probability for this line?

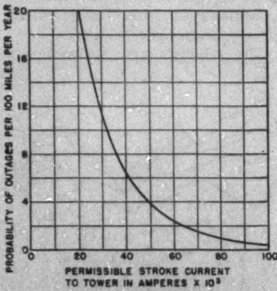

Figure 5. Curve for determining the outage probability if the permissible stroke current to midspan is more than twice the permissible stroke current to tower

From the probability curves, Figure 1(e), for 1,000-foot spans the outage probability corresponding to 10 insulators and 10 ohms tower footing resistance is 0.8 outage per 100 miles per year. For 10 insulators and 20-ohms tower footing resistance the outage probability is 3.0. The outage probability for strokes to tower along the entire line is (0.20 by 0.8) + (0.80 by 3.0) = 2.56 outages per 100 miles per year. The permissible stroke currents, Figure 1(e), to tower are 98,000 and 68,000 amperes for 10-ohms and 20-ohms tower footing resistances respectively.

From Figure 1(i) the outage probability is 1.0 outage per 100 miles per year for 1,000-foot spans with a midspan clearance of 24 feet. The permissible stroke current is 94,000 amperes.

The outage probability for strokes to tower and midspan is 1.78 outages per 100 miles per year for an isoceraunic level of 30; this is the average, (2.56 + 1.0)/2, of tower and midspan outage probabilities.

The outage probability for an isoceraunic level of 50 is 50/30 by 1.78 = 2.96 outages per 100 miles per year. This is the performance that should be expected of this transmission line.

Example II. A 33-kv wood-pole line, shielded by ground wire, located in a territory where the isoceraunic level is 30 has two $5^3/_4$-inch spaced suspension insulators per string. The minimum flashover path for any phase conductor is the porcelain plus 4 feet of wood. The average span is 200 feet and the midspan clearance 8 feet. The tower footing resistance is 50 ohms for all poles. The distance between ground wire and bottom phase conductor at the tower is 10 feet. What is the outage probability for this line?

From Figure 6, 4 feet of wood is equivalent to 2.6 insulators. The equivalent insulation of different insulating media may be added for estimating purposes. Thus the equivalent insulation is 4.6 insulators. Since the spacing from ground wire to conductor is considerably less than 30 feet, a correction is needed to compensate for the increased coupling. From

Figure 4 the correction factor for a 10-foot spacing is 0.75. The effective insulation becomes 4.6/0.75 = 6.15 insulators.

From Figure 1(a) the outage probability for strokes to tower for 6.15 insulators and 50-ohms tower footing resistance is 12.6 outages per 100 miles per year; the permissible stroke current is 36,000 amperes.

From Figure 1(i) the outage probability for strokes to midspan for a 200-foot span with an 8-foot midspan clearance is 0.3 outage per 100 miles per year; the permissible stroke current is 120,000 amperes.

Since the permissible stroke current to midspan is more than twice the permissible stroke current to tower, strokes to midspan may cause flashovers and consequently outages at the tower. For this case, the outage probability is determined from Figure 5. The outage probability for a permissible stroke current to tower of 36,000 amperes is 8.0 outages per 100 miles per year. This is the outage probability assuming all lightning flashovers result in sustained power follow and trip-out. Since part of the insulating medium is wood, approximately 50 per cent of the flashovers will result in outages. Thus the outage probability is 0.50 by 8.0 = 4.0 outages per 100 miles per year for this line.

Example III. A transmission line is being constructed in a territory where the isoceraunic level is 30. The line will be shielded by ground wire and it is desirable to insulate the line so that outages due to lightning will be limited to 2.0 per 100 miles per year. A knowledge of existing lines in the territory indicates that tower footing resistances of 20 ohms can be obtained economically. Due to the choice of towers and conductors the average span will be 800 feet. The conductors and ground wire will be sagged to provide a midspan clearance of 18 feet. How many insulators are required to limit the outage probability to the desired number?

From Figure 1(i) the outage probability for strokes to midspan is 1.0 outage per 100 miles per year. The outage probability for strokes to tower must be 3.0 so that the over-all outage probability will be 2.0 outages per 100 miles per year. From Figure 1(d), the probability curves for 800-foot spans, nine insulators are needed for an outage probability of 3.0 when the tower footing resistance is 20 ohms. Thus nine insulators should limit the outage probability to 2.0 per 100 miles per year.

Basis for General Curves

Computer Study. To determine the tower-top and midspan potentials for strokes entering at those points respectively, a typical transmission line was set up on the electric analog computer.[6] Stroke currents were applied at tower and midspan and the corresponding potentials measured.

The computer set-up is shown in Figure 7, in which part (a) shows the line being represented and the stroke locations assumed. In part (b) is shown the analog or equivalent circuit of the transmission line, at the bottom, and the analog of the stroke, or surge current generator at the top. It will be noted that only the ground wire, tower, and footing constants are represented, the phase conductors having little effect on the ground wire potentials to ground caused by the stroke. Later the coupling is considered in determining the resulting voltage from ground wire to phase conductor.

In the operation of the Anacom, the forcing function which is the stroke surge current in this case, is repeated periodically so that the solutions, that is, the tower-top and midspan potentials, can be displayed on a cathode-ray oscillograph for observation and measurement. They are photographed for permanent records. Typical records of the stroke current waves and of the tower-top and midspan potentials are shown in Figure 8. Impedance in the transmission line analog are low compared with those in the current wave analog so that the line parameters can be varied over the desired range without altering the stroke current. In general, sufficient pi sections are used for the ground wire representation so that further subdivision has negligible effect on the results. Also a sufficient number of spans is represented so that further spans have a negligible effect. Advantage is taken of symmetry so that the line on only one side of the stroke needs to be represented.

The results of this study are summarized in Table I which gives the tower-top and midspan potentials per unit of stroke current, and the equivalent time lag referred to a $1^{1}/_{2}$—40 chopped wave.

Analysis Based on Computer Study. The outage probability curves were obtained from the results of the computer study in the following manner. To determine the insulators required to prevent flashover for any particular value of stroke current to tower the following relationship was utilized.

Insulation strength = stroke current × tower-top potential per unit stroke current × (1-coupling)

For this insulation strength the number

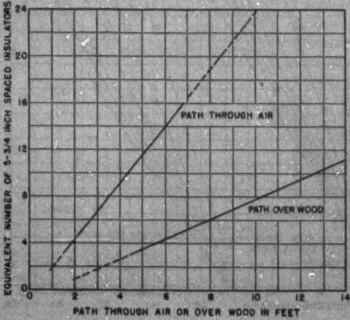

Figure 6 (left). Curves for converting wood and air insulating media to equivalent insulators

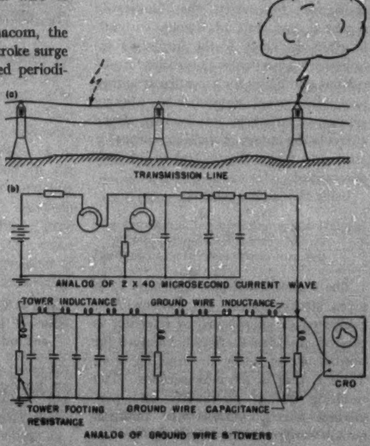
Figure 7 (right). (a) Lightning surging transmission line, and (b) current wave analog surging transmission line analog



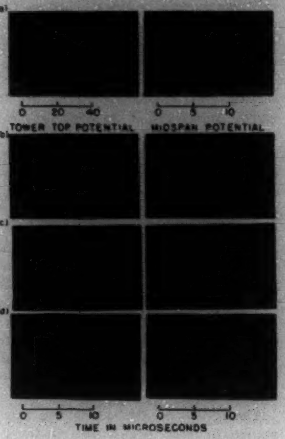


Figure 8(a). 2×40 microsecond current wave;

(d) 2,000-foot span, 100 ohms tower footing resistance

of insulators was then determined from the insulator curves of Figure 9, for positive waves using the time lag from Table I. The probability for this stroke current is given in Figure 2. Thus for a particular span length and tower footing resistance, for which the "tower-top potential per unit of stroke current" is given in Table I, the insulators required for a particular permissible stroke current and hence for a particular outage probability were determined. Making similar calculations for various stroke currents the outage probability curves for strokes to tower, Figure 1(a) to (h) were determined.

Using the similar relation,

Insulation strength required at midspan =
stroke current × midspan potential
per unit stroke current × (1-coupling)

The required midspan insulation for a given stroke current was obtained and converted to air spacing by referring to the rod gap characteristics, Figure 9 for positive waves, using the time lag from Table I, that is, 2.0 microseconds. The resulting outage probability and permissible stroke current for midspan strokes were plotted in Figure 1(i) and (j).

Stroke Current Magnitude and Wave Shape. The stroke current probability curve used is given in Figure 2. It is essentially that published by Waldorf[2] except that it has been modified slightly in the higher current region to allow for strokes up to 200,000 amperes which are known to occur from other field data. The reason for using these data rather than averaging other field data is that the figure of approximately 100 strokes per 100 miles per year for an isoceraunic level of 30, which is used to convert the percentage distribution curve to actual strokes per 100 miles exceeding certain values is based on these same data. However, for the more important high stroke current region, these data were in close agreement with the field measurements of stroke currents to wood pole lines.[7] A 2—40 microsecond current wave was used throughout this study as representative of the more severe lightning stroke currents of importance in estimating the lightning outages of transmission lines.

Ground Wires. The number of ground wires used to shield phase conductors is relatively unimportant as long as all conductors are properly shielded.

Figure 10 shows the relative positions of ground wire and phase conductors which permit 0.1 per cent exposure of the conductors. The general curves assume the shielding to be 100 per cent effective or that no strokes terminate on phase conductors. If the shielding[8] is inadequate strokes terminating on phase conductors must be added directly to the outages given by the general curves.

Consider a transmission line with two ground wires. Since strokes to midspan usually involve only one ground wire, the voltage across the insulation at midspan will be independent of the number of ground wires. For strokes to tower, the voltage across the insulation depends partly on the surge impedance of the ground wire and coupling between ground wire and conductor. Two wires in parallel have a lower surge impedance and higher coupling factor than a single wire; both of these factors tend to lower the voltage across the insulation. However, they are both minor factors as the voltage across the insulation depends principally on stroke current magnitude, tower inductance and tower footing resistance. Thus, the voltage across the insulation at tower will be slightly more for a line with a single ground wire than a line with two ground wires, other parameters being equal. For this reason, a transmission line with a single ground wire 1/2-inch diameter, 100 feet above the ground, having a surge impedance of 550 ohms is used for this study.

Towers. A separate study was made on the Anacom to determine the proper tower representation. The impulse value of tower footing resistance, on which the general curves are based, was represented by a linear resistor. For tower footings of 10 ohms or less the impulse value is only slightly less than the measured 60-cycle value and it is common practice to use the

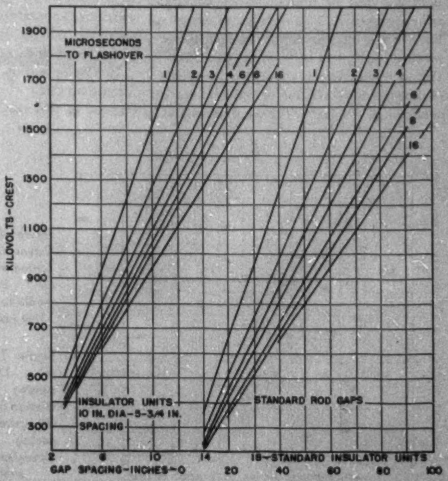

Figure 9. Characteristics of insulators and rod gaps

All values are based on positive waves and corrected to standard atmospheric conditions latter. For higher values the 60-cycle resistance should be converted[11,13] to the equivalent impulse value since the latter may be appreciably less than the former. The tower inductance of 20 microhenries, used throughout the study, was represented by inductance coils. This value represents a steel tower roughly 100 feet high assuming 0.2 microhenry per foot or a wood pole 50 feet high with a down lead taken as 0.4 microhenry per foot. Figure 11 shows the number of insulators required for different values of tower inductance. Tower capacitance to ground was neglected since it did not affect tower-top potential.

Coupling. The entire ground wire or tower-top voltage does not appear across the line insulation. A voltage is induced on the conductors of the same polarity as the ground wire voltage. The ratio of this induced voltage on the conductor to the ground wire voltage is the coupling factor. Thus, the voltage across the insulation is the ground wire voltage times (one minus coupling factor), neglecting normal frequency voltage.

Since coupling decreases as the distance from ground wire to conductor increases, the voltage across the insulator string of the conductor farthest from the ground wire will be greater than the voltages across the other insulator strings. This assumes that the ground wire and tower-top are at the same potential. A distance of 30 feet between ground wire and farthest conductor was assumed for calculating coupling factors.

The electromagnetic and electrostatic coupling factors are equal unless the effective radius of the ground wire is increased by corona, then the electrostatic coupling becomes greater and the electromagnetic coupling is believed to be unaffected. The coupling factor with corona considered is computed by the formula, coupling = $\sqrt{\text{electrostatic coupling} \times \text{electromagnetic coupling}}$; this is the geometric mean of the coupling factors.

The coupling is calculated by the equation

$$C = \frac{\log b/a}{\log \frac{2h}{r}}$$

where

C = coupling factor
b = distance from conductor to image* of ground wire
a = distance from conductor to ground wire
h = height of ground wire above ground
r = radius of ground wire

The electromagnetic coupling factor is calculated by using the actual radius of the ground wire, the electrostatic coupling factor is calculated by the same equation using the effective radius of the wire due to corona.

The effective radii of the ground wire due to corona are given by McCann.[9] The data in this paper are based on laboratory test with potentials up to 2,000,000 volts and then extrapolated so that the effective radii can be determined for potentials up to 6,000,000 volts. Using these effective radii the electrostatic coupling factors were calculated; the electromagnetic coupling factors were calculated using the actual radii. The geometric mean of these coupling factors was used in calculating the voltage across the insulation.

For strokes to midspan the ground wire voltage may exceed 6,000,000 volts. To determine the coupling for these higher voltages, the coupling factor versus voltage curves were extrapolated conservatively. The coupling increased with voltage to 7,000,000 or 8,000,000 volts and then remained constant for higher voltages. With this conservative extrapolation the coupling factors used for the higher ground wire voltages were not too large.

The Effect of Ground Wire to Conductor Spacing at Tower on Insulation Required. In calculating the coupling factors for the ground wire and phase conductor which is most likely to flashover, a 30-foot spacing was assumed. If the spacing is less than 30 feet the coupling factor will be larger, and consequently the voltage across the insulator string will be less. A means of correcting for the spacing is provided since a 30-foot spacing is not representative for all line configurations.

Coupling factors were calculated for spacings ranging from 5 to 50 feet for a particular ground wire potential. The voltage across the insulation and in turn the number of insulators required were determined. From this the ratio of insulators for a 30-foot spacing to the equivalent insulators for the particular spacing was determined. This was done for ground wire potentials ranging from 500,000 to 3,000,000 volts. The ratios were found to be almost independent of ground wire potential. Thus the average of the ratios for a particular spacing can be used irrespective of ground wire potential and not cause serious error.

These average values are plotted in Figure 4. By using the correction factor for the particular spacing, the general curves are applicable for all practical line configurations.

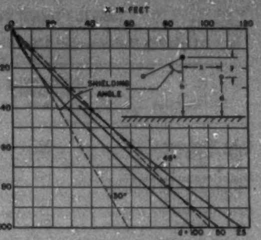

Figure 10. Configuration of shielding wire with respect to protected phase conductors for 0.1 per cent exposure

This correction factor also can be used for insulating the phase conductors so that all conductors have equal probability of flashover. The conductor nearest the ground wire will have the largest coupling factor and consequently the lowest voltage across the insulator string; thus fewer insulators can be used. If the insulation required for each phase conductor is determined in this manner, all phases have equal probability of flashover.

Tower Flashovers Due to Midspan Strokes. If the permissible stroke current to midspan is more than twice the permissible stroke current to tower, strokes to midspan may cause tower flashovers. Figure 5 provides a means of estimating the outage probability in such cases. This probability curve treats a current entering the tower through wire the same as a current of equal magnitude entering the tower through a stroke terminating on the tower.

This is not strictly true because the tower current will be reduced by reflected waves from both sides of the tower if the stroke is to tower. However, if the stroke is to midspan, the tower current will be reduced by reflected waves from one side of the tower only since the stroke channel is assumed to be of infinite impedance. However, this is a minor factor which can be neglected without causing serious error.

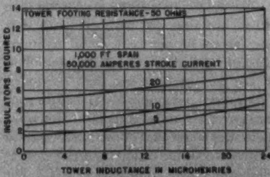

Figure 11. The effect of tower inductance on the number of insulators required

5$^{3}/_{4}$-inch spaced insulators	50	2,000	30	3.7	3.4

† Basic insulation level.

** 6.8 for strokes to tower; 1.1 based on midspan, method not given for combining in case of noncoordination. Practice has been to average when estimates for tower and midspan not too far apart.

Wood and Air Insulating Media. For wood pole lines, the line insulation may be provided by a combination of porcelain, wood, and air. In this case it is necessary to find the equivalent number of insulators so that the general curves can be used. If the basic insulation level of the line is known, the equivalent number of insulators can be found from Figure 9. If not the probable flashover path must be determined. If the flashover path is through air or over wood, the equivalent number of insulators can be found from Figure 6. For estimating purposes it is sufficiently accurate to add the equivalent insulators of the different insulating media and use this value in the general curves.

Lightning Flashover and Power Follow. All lightning flashovers do not result in sustained power follow. The percentage of flashovers that result in power follow depends principally upon the type and length of the insulation path, the magnitude of the power follow current and the magnitude and duration of the lightning flashover current. Performance records[2] on various types of lines have yielded some data on the ratio of sustained power follow to flashover.

For the higher voltage, steel tower lines where the principal flashover path is in air, about 85 per cent of all lightning flashovers result in sustained power follow if the line length is less than 100 miles. The ratio is reduced to about 0.50 for such lines over 200 miles in length. For wood pole lines where part of the flashover path is over wood, the ratio of power follow to flashover ranges from 0.35 to 0.50. For 13- and 33-kv wood pole lines Ekvall[10] shows the sustained power follow to be a function of the length of flashover path divided by the normal frequency voltage.

If the characteristics of the line and line insulation result in a considerable reduction of the ratio of power follow to flashover, this should be considered in estimating the outage probability. To determine the outage probability taking this factor into account, multiply the ratio of power follow to flashover by the outage probability from the general curves. If the ratio is near unity, it can be neglected and the general curves will indicate a slightly pessimistic outage probability.

Experimental Verification. The general curves give results which are in accord with practically all of the published information on actual line performance. They are also in general agreement with the previous curves of Monteith except for the short spans and high-tower footings where some changes are required. In general it is known that 33-kv lines with basic insulation level of 700 kv and 10-ohms tower footing resistance result in two or three outages per 100 miles per year. The 132-kv lines of usual lightning-proof construction will have about one outage, and 220-kv lines with overhead ground wires and low-tower footings are practically lightningproof, having a small fraction of one outage per 100 miles per year.

Table II shows the predicted values from the new estimating curves for several typical cases, together with values from the earlier curves of Monteith. It will be noted that the new curves show slightly fewer flashovers for the more important case of 10-ohms tower footing. They indicate considerably more flashovers with high-tower footing since the stroke current treatment allows for no suppression of the stroke current by the high-footing resistance.

Conclusions

A method for estimating the lightning performance of transmission lines is presented. This method is based on the stroke current probability data and takes into account all the line parameters believed to affect the performance materially. The general curves with some auxiliary curves cover the complete range of transmission line designs.

The general curves may be used for estimating the performance of existing transmission lines or may be used for comparing the relative merits of changes proposed to improve the lightning performance of existing lines. The curves also may be used for estimating the insulation requirements of lines being designed for a predetermined lightning performance.

Discussion

P. L. Bellaschi (Consulting Engineer, Sharon, Pa.): Much in the way of labor and mathematics that normally would encumber a contribution of this character have happily been dispensed through the application of the electric analog computer. It would seem too that no excessive claims are made for the curves other than as a means of estimating purposes. In view of this and because of its simplicity and practical approach to the general problem, this paper by Harder and Clayton is well worthy of attention.

The following points have reference especially to the conditions surrounding the problem—for the end results are no better than the assumptions imposed. The basis of the analysis is summed up in the third paragraph under "General Curves." An examination of the curves in Figure 1 indicates that for 230-kv as well as 138-kv and 115-kv lines of usual design, the ratio of flashovers at midspan to tower-insulator flashovers is entirely on the high side. Referring to 230-kv design: 1,000-foot span, 32-to-36 foot clearances at midspan between line and ground conductors, 14 standard insulators and about 15-ohm tower footing resistance, according to the curves the relative flashovers at midspan and across the insulators at the tower are nearly the same. Field observations in general do not seem to bear this out. Because of the obvious practical difficulties, it could well be that midspan conductors have not been inspected in the past as diligently as at the tower position. To this we could add that long air spacings might be a factor in power quenching at midspan. Nevertheless, the high ratio of midspan to tower flashovers in the calculated curves very likely can be accounted in good measure from the assumptions imposed. One of these is that "a 2 by 40 microsecond current wave was used throughout the study as representative of the more severe lightning-stroke currents of importance in estimating the lightning outages of transmission lines." A second consideration affecting the results is the effect of the coupling factor between ground and line conductors at midspan and the fact that the data had to be extrapolated from 2,000,000 to 7,000,000 or 8,000,000 volts. Accordingly these assumptions bear further consideration. For instance, on the basis of average probability, a 2-microsecond front might in effect be too steep. Furthermore, there is some question as to whether the characteristics of the lightning stroke such as the surge impedance can be dispensed entirely.

It is clear that we do need more experimental data, especially in regard to coupling factors between conductors, up to possibly 8,000,000 or even 10,000,000 volts, and in regard to impulse sparkover for spacings 20, 30 and 40 feet. These as well as the related problems of grounds, power-quenching characteristics of wood and air, and so forth, can probably be settled economically and effectively in part through experimental work in the field conducted with portable lightning-stroke generators as it was indicated in the discussions at the Montreal summer meeting.[1]

It is well too to point out here that in estimating the lightning performance of a line due consideration has to be given to the distribution of lightning strokes along the entire length of the line, in the span and at the tower, to the effect of topography and terrain, and to similar factors. The significance to attach to Figure 3 is a matter that has to be weighed locally. To illustrate one instance, in a 230-kv line recently studied in some detail, practically all the strokes to the line were found to occur concentrated in two regions (creeks) which the line traverses, thus affecting only about 50 per cent of the total length of the line. Furthermore in this case the terrain plays a very important role.

In regard to the ratio of power follow to lightning flashovers, the paper gives a figure of 0.50 for lines over 200 miles in length. This figure, I would judge, is on the optimistic side insofar as it applies to high-voltage steel-tower construction. On the other hand, wood definitely offers possibilities of this order, and even greater advantage, as was discussed rather fully at a previous meeting.[1] Finally one can venture in saying—and this should not detract from the contribution under discussion—that in estimating line performance to lightning the method involving current in place of lightning voltage has been in use by the various investigators, Bell, Bewley, Waldorf, and others, in one form or another, for some time in the past.

1. Lightning and 60-Cycle Power Tests on Wood-Pole Line Insulation, P. L. Bellaschi. AIEE Transactions, volume 66, 1947, pages 838–50.

F. E. Andrews (Public Service Company of Northern Illinois, Chicago, Ill.): This paper is an especially timely step in progress of transmission line design because it brings practical field methods up-to-date to take into account the advances in knowledge and scope of application since Monteith's original work.[1] Extension to cover short-span wood pole lines is especially pertinent.

It may be of interest to report experience with shielding angle in relation to Figure 10.

In reference 7, the performance of 33-kv wood pole triangular construction with protector tubes on the pole top conductor (type III, Figure 9) is described. The x and y dimensions on Figure 10 for this construction are 4.6 feet and 6.2 feet respectively, which fall approximately on the $d=25$ foot curve, indicating good shielding. The operation of these lines has shown practically perfect shielding.

Figure 4, for coupling factor correction, makes use of the spacing at the tower between conductor and ground wire. It is assumed that the y dimension in Figure 10 also is intended to be taken at the tower. The question arises as to how differences in sag are taken into account. Were the curves based on average assumptions for midspan separation in relation to spacing at the tower, or is this difference unimportant?

Another question on which clarification seems desirable, is that of the wave shape used. It is stated that insulation flashover values and calculation of tower top potentials are based on $1^1/_2$ by 40 waves. In the section Stroke Current Magnitude and Wave Shape, reference is made to the use of a 2 by 40 current wave. An explanation to reconcile this apparent difference would be helpful.

1. See reference 1 of the paper.

L. V. Bewley (Lehigh University, Bethlehem, Pa.): The authors credit their associates, G. D. McCann and C. F. Wagner,[1] with having introduced the new method of using the lightning current, rather than the lightning voltage, as the parameter in calculating the lightning performance of transmission lines. In the opening paragraphs they speak of a still more fundamental approach leading to a general analysis in which the stroke current itself is used as a parameter. They also speak of their present paper as a refinement of Monteith's "complete set of estimating curves covering the full range of insulation levels, span lengths, and tower footing resistances encountered on transmission lines." May I point out that in reference 4 of the paper, which was published in 1937, and which itself was based on a previous paper, "Flashovers on Transmission Lines,[2]" I used the lightning current expectancy curve; gave the equations for placing all calculations on the basis of stroke currents, provided general formulas and estimating curves for strokes to towers and to midspan which included insulation, length of spans, coupling factors, tower footing resistance, and a factor to account for the effect of successive reflections; and in addition included the influence of the normal frequency voltage. The flashover equation given in reference 4 is

$$V=(1-C_s)\alpha R'I+e$$

in which

V = voltage across insulator
C_s = coupling factor (depends upon the number, configuration, and spacing of the conductors, and is modified by corona)
α = crest factor (depends upon the length of spans or the distance between expulsion gaps, tower footing resistance, lightning wavefront, and conductor surge impedance)
R' = effective resistance (depends upon the grounding resistance, and the surge impedance of the lightning stroke and of the stricken conductors)
I = lightning current which the stroke could deliver to a zero-resistance ground (which is equal to twice the traveling-wave current in the stroke)
e = effective instantaneous normal-frequency voltage (depends upon the normal-frequency polarities and the conductors involved)

Now the voltage at the stricken point is given by either $R'I$ or RI_B. But if we assume our lightning expectancy curve to be the total current delivered to all towers and ground wires we must use $R'I$. If, on the other hand, the expectancy curve refers to tower current only, then we have to use RI_B. But suppose this same stroke had hit a very high resistance ground. It would not deliver the same current. It is, therefore, highly preferable to base calculations on the current which the stroke could have delivered to a zero resistance ground, and to use a current expectancy curve with that understanding.

The authors include the inductance of the tower, but ignore the tower capacitance ". . . since it did not affect tower-top potential." Would the authors ignore the capacitance of the line conductors on the same basis? Actually the tower is a surge impedance of perhaps 100 ohms, and in the course of a few reflections (say, 0.5 microsecond) this surge impedance is wiped out, so that only the tower footing resistance remains. Since the crest of a 2/40 wave is substantially constant over a 0.5 microsecond interval, the tower surge impedance may be ignored. I believe the first to calculate the surge impedance of a tower was C. L. Fortescue.

The authors refer to G. D. McCann (reference 9 of the paper) for data pertaining to the effective radii of a ground wire with corona, and fail to state the origin of the geometric mean formula for the coupling factor with corona present. I believe the first to investigate the increase in diameter due to corona was E. M. Hunter.[3]

The minimum insulation of a line should be based on the maximum switching surge that can occur on the system, rather than on lightning surges (see Figure 4 and accompanying text in reference 4 of the paper). It is far cheaper to secure immunity from lightning by lowering the tower footing resistance than by increasing the insulation. A rule of thumb is "one ohm reduction in tower footing resistance is equivalent to one insulator disk."

3. THE EFFECT OF CORONA ON GROUND WIRE PROTECTION, E. M. Hunter. *General Electric Review* (Schenectady, N. Y.), volume 33, February 1930.

E. L. Harder, J. M. Clayton: Andrews asks clarification of the use of the coupling-factor correction curve of Figure 4. This curve is used only for estimation of outages caused by strokes to the tower. Consequently it is the coupling factor at the tower which is being determined and the abscissa of Figure 4 refers to the ground wire to conductor spacing at the tower.

The estimating curves given for outages due to strokes at midspan involve midspan spacing from ground wire to phase wire as a parameter, see Figure 1, (i) and (j) and no single value was assumed for the midspan case. Hence no coupling factor correction curve is needed for the midspan estimates. The coupling factors used correspond to the actual midspan clearance with corona effect included.

Andrews' second question concerns wave shape. The 2—40 microsecond current wave was taken as most representative of the average severe lightning stroke current. With this wave introduced into the line the resulting voltage is not a 2—40 wave but is a complex shape dependent upon the impedances, reflections, and so forth. Typical resulting voltage waves are shown in Figure 8. The insulation is exposed to these voltages of complex shape and the problem is then to determine how much insulation is required to stand this voltage. The strength of insulating elements, wood, porcelain and air, is known and cataloged generally only for the $1^1/_2$—40s tandard wave. The strengths are known for full $1^1/_2$—40 waves and chopped $1^1/_2$—40 waves. The complex voltage wave must be converted to an equivalent standard wave so as to refer to the available data on insulation. There is no standardized way to make this conversion and the method adopted by the authors was based on a visual examination of the complex waves. As shown in Figure 8 they have the shape of chopped waves. We have therefore taken the equivalent chopped $1^1/_2$—40 wave as one which has the same crest value and has a chopping time corresponding to the time at which the abrupt drop takes place on the voltage oscillograms taken on the computer. These times vary somewhat from case to case and are given in Table I of the discussion. They are not less than two microseconds because no drop occurs as long as the surge current is rising, and are longer for high footing resistance with span above 1,000 feet. In these cases the reflections from adjacent towers are important and occur later than two microseconds.

At midspan the abrupt voltage drop corresponds to the cessation of surge current rise and is two microseconds for the 2-40 current wave used.

A careful analysis indicates that this relatively simple conversion of the experimentally determined voltage wave into an equivalent standard wave is as accurate as is needed or justified for this problem.

Bellaschi has raised a question regarding the relative number of midspan and tower flashovers predicted by the estimating curves. This is an important point and one which was given considerable study. His question applies to "230-kv as well as 138-kv and 115-kv lines of usual design". These we would like to discuss.

Consider first 230-kv lines. For a midspan clearance of 32 feet the curves give 0.2 flashovers per 100 miles per year based on half of the strokes occurring to midspan. They indicate that a stroke current of 116,000 amperes, occurring right at midspan is necessary to cause midspan flashover. This probability is extremely low which is in agreement with experience.

As to the experimental ratio of tower to midspan flashovers, two factors must be considered. First, more flashovers have occurred from lack of shielding than from insulation flashover by strokes contacting the ground wire on some 220-kv lines. For example, on the Pennsylvania Water and Power Company 220-kv lines "Three flashovers have occurred, two from lack of shielding, and one at a tower having a tower footing resistance of about 60 ohms."[1] The curves of Figure 1 predict only outages caused by strokes contacting the ground wires. All direct strokes to phase wires due to lack of shielding cause tower flashovers.

The second point is that some of the flashovers occur at towers where the footing is exceptionally high, and the case cited above is an example. In this case a stroke current of lower magnitude and far greater probability causes the outage and it is at the tower. The tower flashover probability can be considerably increased by a few towers of high footing, but the tower footing has very little influence on midspan flashover. Thus the only three cases of a flashover of these lines give no indication of the ratio of midspan flashovers to tower flashover for strokes contacting the ground wire on a line having a uniform 10-ohm tower footing. This probably explains the higher ratio of tower flashovers.

As pointed out in the paper total flashovers are the sum of those caused by lack of shielding and those caused by strokes contacting the ground wire. The latter are given by the general curves published in the paper and the former in reference 8 of the paper from which Figure 10 is derived.

Hansson and Waldorf[2] have analyzed a number of cases of midspan strokes of high current and have found that none caused midspan flashovers. These were cases in which large, substantially equal currents in two adjacent towers indicated the stroke to be to the ground wire of midspan. Lines from 66 kv to 220 kv were involved. These data are given in Table I of this discussion together with the midspan clearance required to prevent flashover according to the estimating curves given in Figure 1 (i) and (j) of this paper. Note that in 16 of the 17 cases the curves of the present paper also predict that the currents involved would not cause midspan flashover. Thus the curves are in good agreement with the Waldorf-Hansson data regarding the number of midspan flashovers.

Bellaschi questions the treatment of the characteristics of the lightning stroke and suggests the use of the stroke surge impedance. The constant current concept which assumes a high impedance stroke channel has been the basis for estimating line performance for a number of years and the authors believe this to be the best representation based on the present knowledge of the stroke channel. The stroke channel can be represented more accurately when more has been learned about it from field research.

Bellaschi points out that the distribution of lightning strokes along different lines varies depending on topography, terrain, and similar factors. This is quite true, but such considerations apply to a particular line and can not be considered in a general estimating method. The isoceraunic map of Figure 3 is the best available data for determining the average thunderstorm distribution neglecting minor factors that may influence a particular line.

Bellaschi questions the ratio of power follow to lightning flashovers of 0.50 for the steel tower lines over 200 miles in length.

Field data of this nature are quite incomplete and no attempt is made to cover this subject thoroughly in the paper. The subject is discussed in more detail in references 3 and 10 of the paper.

Bewley points out that in 1936 he published an estimating method based on the stroke current probability curve. The authors recognize that estimating methods based on lightning currents have been published previously. The general considerations of estimating method are discussed in the introduction of the paper.

Bewley's method is based on the stroke current which is taken to be dependent upon the terminating resistance. Also his method

requires the assumption and use of a stroke surge impedance.

The constant current method used in the paper assumes the stroke current to be independent of the terminating resistance. The authors do not believe this assumption results in appreciable error since the stroke current magnitudes recorded on lines of various tower footing resistances do not vary appreciably for the practical range of tower footings. Also the stroke current probability curve was obtained from strokes to transmission lines with tower footing resistances within the practical range. Thus no modification of the stroke current magnitude is needed for stokers terminating on lines with tower footings of the same order.

This method also assumes that traveling waves on the transmission line are not affected by the stroke channel. The velocity of the return stroke up the stroke channel is approximately one-tenth that of light. Thus the stroke channel behaves as a constant current source rather than a surge impedance.

Bewley states that "the tower surge impedance may be ignored." The study on the Anacom does not indicate this to be true.

For low (5 to 20 ohms) tower footing resistances, the tower top potential is increased appreciably by the tower inductance and can not be neglected. The tower capacitance was not ignored. It was considered and was varied from zero to the equivalent of several hundred feet of ground wire. Since it did not affect the tower top potential, it was eliminated from further studies.

The coupling factors measured by G. D. McCann are substantially the electrostatic coupling factors. The electromagnetic coupling factor is believed to be unaffected by corona and may be calculated by a conventional formula. With the electrostatic and electromagnetic coupling factors calculated independently, the coupling factors for practical considerations can be calculated from the equation given by Sunde[3] in his discussion of the McCann paper.

Outage Rates of Steam Turbines and Boilers and of Hydro Units

AN AIEE COMMITTEE REPORT

THIS report makes available the forced outage data collected by committees of the Edison Electric Institute. It should promote an understanding of the definitions used in the collection of these data, which understanding is necessary if the data are to be properly used in calculations of system generating capacity requirements.

Part I, containing the steam turbine and boiler forced or emergency outage data collected by the Prime Movers Committee, Edison Electric Institute, was compiled by Philip Doane of the Consolidated Edison Company of New York, Inc.

Part II, containing comparable hydro unit data collected by the Hydraulic Power Committee, Edison Electric Institute, was compiled by E. S. Loane of the Pennsylvania Water and Power Company.

Part I. Forced Outage Rates of Steam Turbines and Emergency Outage Rates of Steam Boilers*

Classification of Outages in Edison Electric Institute Survey

The data collected apply to electric systems on which decreases in load at night and on Saturdays, Sundays, and holidays permit completion of all desired cleaning and minor maintenance work which can be postponed to such short intervals. All outages confined to light load hours of one day are excluded from the data. Outages on Saturdays, Sundays, and holidays have been given special treatment.

Outages widely controllable as to time of occurrence, which were or could have been postponed from one season to another, so that they could be fitted into the seasonal curve of load, were classified as scheduled turbine or overhaul boiler outages. These do not enter into the calculation of contingency reserve requirements; but many systems now find that capacity must be provided just to cover overhaul.

Boilers often require to be regularly cleaned and repaired once in every few months, so that provision for this must be made during the peak-load season regardless of time available in light-load seasons. Such outages, controllable as to time of occurrence within the cycle period of several months, which were or could have been postponed for several weeks were classified as boiler maintenance outages.

Maintenance outages can be scheduled to avoid encroaching on needed contingency reserves. On some systems they can be fitted into unused contingency reserve, while on other systems the amount of maintenance outage is so great that any emergency outage must be covered by additional reserve.

Work on turbines which could be confined to night-time light-load periods or to weekends is sometimes done for convenience during heavy load hours of weekdays. A transferable outage classification was provided for such cases.

All outages not covered by the foregoing classifications were considered to be forced turbine or emergency boiler outages. The separate tabulation of outage existing on weekdays made special classifications for "weekend work" unnecessary.

Turbine outages were also classified as chargeable to the turbogenerator unit, including its condenser and its own auxiliaries; or as chargeable to other cause, such as flood, bus failure, boiler or transmission line unavailability, or reconstruction to alter frequency or capacity as contrasted with rebuilding because of excessive failure rate.

Boiler outages were similarly classified as chargeable to the boiler, including its own piping and auxiliaries; or as chargeable to other cause, except that when a boiler was not operated because of turbine unavailability, the boiler was classified

Paper 49-112, recommended by the AIEE power generation and system engineering committees and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted November 16, 1948; made available for printing January 6, 1949.

This report was prepared by the AIEE joint subcommittee on application of probability methods to capacity problems.

Personnel of subcommittee: G. Calabrese, *chairman;* W. R. Blakeley, H. Duryea, R. G. Hooke, H. A. Lott, W. J. Lyman, K. W. Miller, H. W. Phillips, C. A. Roberts, H. B. Smith, H. P. St. Clair, G. M. Tatum, V. A. Thiemann, C. W. Watchorn.

as available but idle, rather than as out for other cause.

Reduction in boiler capacity by a major fraction because of mill or fan outage, and so forth was reported as partial outage. Reduced capacity operation of turbines was reported occasionally but was too infrequent to justify tabulation.

Questionnaires requested that when forced or emergency outages were extended to do general overhaul work, the time required for the forced or emergency repair be estimated and separated from the continuation as overhaul.

Provision was made for reporting days on which the turbine or boiler was operating, idle, or not installed.

The definitions for the various outage classifications were in general terms. (See Appendices I and II). In response to requests for some more definite if arbitrary demarkation, the following tabulation was included with the questionnaire instructions for reporting of 1941 and subsequent years:

	Criterion Postponability Approximately how long could outage have been postponed and rescheduled?	Criterion Predictability Is outage of kind for which advance provision is made as routine?	Classification
A–Turbogenerators			
	2 months or more		Scheduled
	Under 2 months		Forced
B–Boilers			
	2 months or more		Overhaul
	2 weeks to 2 months	Yes	Maintenance
	2 weeks to 2 months	No	Emergency
	Under 2 weeks		Emergency

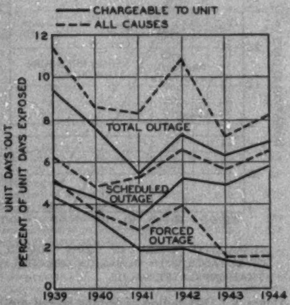

Figure 2. Turbine weekday outage rates yearly 1939–1944 for units with pressure 1,000 pounds per square inch or more

Transferable outage, not separately shown, included in total

Forced Turbine and Emergency Boiler Outage Rates

It has been assumed that turbine and boiler outage occurrences and outage times are proportional to the number of days on which the units operate. Thus, a day on which a unit started up and shut down twice, for a total of four hours of operation, is equated to 24 hours of operation without start-up or shutdown as a measure of the risk of outage. Use of the days on which a unit is in operation rather than of the hours in operation, or of the output per unit of capacity does give recognition to stresses in starting up and shutting down.

Summaries of the basic outage data are given in Tables I and II including data for all days as well as for weekdays. Figures 1 to 4, inclusive, show annual values of the several weekday outage rates. The small size of the annual sample for the high-pressure units is a factor in the variability of the corresponding outage rates.

For some calculations of capacity requirements the distribution of the outages according to length is a factor. Table III shows the summaries of the numerical details of these data and also the adjustment made to exclude an excessive number of "weekend" outages. The adjustment is made on the basis of the rate at which outages of three days or less occur, and are confined to weekdays. The summarized data for the entire period are shown graphically on Figures 5 and 7. Figures 6 and 8, respectively, show similar data, on an annual basis, for the low-pressure turbines and boilers.

Table covers only status during heavy load hours of day.

unit-days operating and unit-days forced out) may be taken from the Table III values as adjusted for excess of weekend outage. In 1939 through 1944 turbines operating for 2,148 unit-years at pressures below 1,000 pounds per square inch had an average forced outage rate of 1.00 per cent; and for 253 unit-years at higher pressures had an average forced outage rate of 1.96 per cent.

In calculating boiler emergency outage rates one method of handling the partial outages is to treat the boiler-days of partial outage as equivalent to one-half that number of boiler-days of full outage as shown in Table III. On this basis the adjusted average emergency outage rate chargeable to the unit, over the period 1940–1944 inclusive, is 1.06 per cent for 1439 boiler-years operating at pressures under 1,000 pounds per square inch, and is 1.94 per cent for 351 boiler-years at the higher pressures.

Discussion

A classification of turbine outage different from the one employed for this report has long been in use by the Prime Movers Committee of the Edison Electric Institute and its predecessor. This older classification primarily distinguished outage during hours when the unit should have been in operation for best efficiency or for capacity needs, known as demand time, from outage during hours when the unit would not have run if it had been available, known as nondemand time. Since the speed with which repair work confined to nondemand time is done has no direct effect on the ability of the system to carry load or on its efficiency, some operators feel that nondemand outage should be excluded in calculating unit availability.

The contrast between demand outage and forced outage may be shown by the following cases. Assume two identical pairs of units, one pair of high efficiency, and the other pair of lesser efficiency. Load conditions are such that two units are needed, preferably the pair of high efficiency. Under the older classification of outages, if one of the higher efficiency units suffered an outage due to a broken shaft, such outage would be a demand outage. If one of the less efficient units suffered a similar outage, such outage would have been classified as a nondemand outage. However, under the classification used in this report, both units are on forced outage since there is no possibility of postponing the outage.

Now, suppose that, while there is nothing specifically indicating that the units could not go on running for another year without trouble, past experience suggests that, in the time since their last overhaul, blade erosion has progressed to a point making replacement desirable. Suppose further that the units are scheduled to be taken out of service at a time

when one unit of each pair can be out while still leaving a surplus of capacity over all requirements, and, that if available two of the four units, preferably the two most efficient would run. Then as before the more efficient unit will be out when in demand and the other will be out when not in demand. But in this case both outages are scheduled rather than forced, since they are taken when convenient.

Outage does not fall into the scheduled class merely because it is possible to postpone it for a few hours while replacement capacity is started, or because it happens to occur at a time when it falls within a surplus of available capacity over that wanted to cover load and all the reserve desired to meet contingencies. The essential feature is that the outage be of a kind that can be postponed for a length of time which would suffice, if the outage occurred at any time of the year, to allow the outage to be fitted into the overhaul schedule. The definition of nonforced outage used by the Hydraulic Power Committee of the Edison Electric Institute requires that the outage be postponable to a previously scheduled normal maintenance period for the unit, or for some other unit for which it might be substituted (or that the outage be confinable to night time or weekend periods). In this definition the required delay is variable with the circumstances of the case. Whether in the interest of uniformity a fixed period be preferable is a matter of opinion.

Valid criticism of the classification rests upon the use of an opinion as to what might happen for the basis of classification.

The criterion of time postponable is necessarily an estimate, even though it may rest on facts as to nature and amount of damage found in the actual repair.

‡Days of full operation plus outage-days, including one-half of total partial outage-days, for kind of outage considered.

There is no way of ensuring absolute uniformity of estimates by different individuals dealing with different units on the basis of different experience. However, the effects of such variations of opinion tend to be neutralized, with a minimum effect on the final results, particularly when a large amount of data is available. It is felt, therefore, that useful results are obtainable for which any deviations that may exist are hardly of sufficient magnitude to have any practical or significant effect on the results obtained by use of these data.

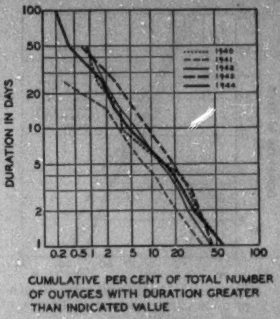

Figure 8. Distribution of boiler emergency outages chargeable to boiler (full plus partial) according to duration after adjustment for excess of weekend outage—boilers with pressure less than 1,000 pounds per square inch year by year

Part II. Forced Outage Rates of Hydroelectric Units*

The reliability of hydroelectric units, insofar as their capacity value is concerned, is a function of the frequency and duration of forced outages arising from mechanical, electrical, or structural failure associated with the units as well as the effects of certain natural phenomena such as low river flow, floods, and ice. This report is concerned only with those outages arising from the failure of the unit itself and which may be typical of all hydro units of the same general type. It is to be expected that the forced outage rate for hydroelectric units would be smaller than for steam-electric generators. In some cases the forced outage rate may be so low as to be negligible in comparison with probability of low-load carrying capability due to drought, floods, ice, or other natural causes, or it may be overshadowed by required outages for maintenance. These factors of river flow and temperature are peculiar to each system and have no significance as averages for a large number of hydro sites; but in most any case the data here reported will provide a reasonable basis for the consideration of hydro unit forced outages in an investigation of system generating capacity requirements.

The forced outage definition used here is essentially the same as that employed in the questionnaire on steam turbine outages. Much of the discussion in Part I of this report, relating to the distinction between different types of outage, is applicable to the data on hydro units. Although it is unnecessary here to supplement the comments and instructions which accompanied the hydro unit questionnaire and which are shown in Appendix III, one difference in the basis of outage rates should be noted.

It is to be expected, all other conditions being equal, that the occurrences of hydro unit forced outage will be approximately proportional to the time of unit operation. Because this quite reasonable assumption can be made with respect to forced outages of hydro units, their operating time and outage time have been reported in hours.

For steam units, however, a different assumption and basis of analysis was necessary. Because the strains of starting and stopping steam equipment are severe, it was felt that time alone was not a fair measure of the hazard of forced outage. It was initially assumed, and later supported by analysis of the steam unit data, that the number of days on which units operated was a more nearly correct measure of exposure than hours of operation.

Consistent with this measure of exposure, outage time was counted only in whole days, forced outage for any interval during the heavy load hours in a calendar day being considered as a day's outage. To provide hydro data on a basis comparable with that used for steam units, the over-all outage rate for hydro units has been determined on this whole day basis as well as on the actual hourly time of operation and outage.

Response to Questionnaire

The collection of forced outage data for hydroelectric units was undertaken in 1941, when a brief questionnaire was distributed to selected utilities in the United States and Canada. General distribution of the questionnaire was made only once; but the recipients were requested to report their forced outage experience for as many years as possible. A number of companies supplied the desired information for several years, some covering the entire experience of their hydro plants. A few utilities have continued to accumulate the outage data and have reported them to the Hydraulic Power Committee of the Edison Electric Institute, from time to time.

Although the study was undertaken at a time when questionnaires were in disfavor, and was not followed up in successive years, the response was sufficient to provide satisfactory indication of over-all outage rates. Data were not adequate, however, for analysis of outages by year of operation, or by size, type, or age of unit. Over 80 per cent of the reported data were for Francis units, the reports for Pelton and Kaplan wheels, being insufficient for separate analysis, were used in the computation of the over-all results.

Contributions of data, covering about 20 per cent of the installed hydro capacity in the United States and Canada, were received from 31 companies, 93 plants, and for 335 units with total capacity of 4,500,000 kw.

Forced Outage Data

The over-all results of the study, analyzed on both the hourly and daily basis are shown in Table IV.

On the whole-day basis the average duration is approximately 0.8 day longer than on the hourly basis, but the per cent outage time remains approximately the same.

The durations of individual forced outages also have been analyzed on the whole-day and actual-time bases. It has not been considered necessary to show hours of outage for durations above 72 hours since such a fine measure for the longer outages would have little significance.

Table IV

	Actual Time (Hourly Basis)	Whole-Day Basis
Unit years of record	1,448	1,448
Time of operation	9,292,300 hours	464,282 days
Forced outage time	42,559 hours	2,020 days
Exposed time	9,334,859 hours	466,302 days
Number of outages	297 hours	297 days
Forced outage in per cent of exposed time	0.46 hour	0.43 day
Average duration of outage	143 hours	6.8 days

Table V. Distribution of Outages by Duration

Hours	Outages	Days	Outages
1	57	1	161
2–4	41	2	34
5–7	25	3	14
8–12	28	4	17
13–24	27	5	8
25–36	14	6–10	24
37–48	5	11–15	11
49–60	11	16–25	9
61–72	9	26–50	10
		51–100	6
above 72	80	over 100	3
Total	297		297

The data shown in Table V include all weekend outages that were reported. Some companies reported such outages as forced, some did not. Analysis of the reported 1- and 2-day outages indicates that those occurring on weekends were somewhat less frequent (as they should be) than those occurring on Monday to Friday, inclusive. No adjustment, parallel to that made in steam unit data, was considered necessary for the hydro units.

An adjustment of the weekend outages, to eliminate them entirely or to approximate the number that should have been reported, would have insignificant effect on the outage rate. Because these are practically all 1-, or sometimes, 2-day outages, they do affect slightly the average duration, but would change the per cent forced outage time by less than 0.01 per cent.

Conclusion

The data presented are basic to determinations of system capacity requirements by probability computations. Applications have been discussed in other publications, particularly in a group of papers[1–4] presented at an AIEE meeting in November 1947. It is hoped that the material presented herein, as well as in these earlier papers, will be of service to those engineers engaged in studies of system capacity requirements, and should be a basis for more extensive use of such methods in the solution of system capacity problems.

Attention has been called to the fact that too few data are available for large, modern high-pressure steam turbines and boilers and for certain types of hydro units. General knowledge of the availability of data such as these and their usefulness in the industry should facilitate the future collection of such needed information. The outage rates reported in Table IV are not necessarily fixed quantities, and it would be desirable to collect further data at reasonable intervals.

Appendix I. Graphic Questionnaire. Summary System—Daily Record of Steam Turbine Operation and Outage[*]

Turbine Subcommittee, Prime Movers Committee, Edison Electric Institute

Reported Outage. In the analysis of reserve problems it is evident that only outages which reduce the margin between the daily peak load and the installed capacity need be considered. Any deficiencies in installed boiler capacity should be disregarded in figuring this margin between load and capacity. In general, any outage, regardless of length, that occurred or existed during the peak portion of the day is to be counted as one full day of outage, while an outage which was confined to off-peak hours of the day should be disregarded. An exception is an off-peak outage which has reduced the margin below that of the peak, so that it should be counted. Cases of successive nonoverlapping outages on the same day will have to be covered by remarks on the reverse side of the sheet. Outage days should be classified as described below.

Reduced Capacity Operation. Cases in which units either after or in anticipation of failure were repaired or altered for temporary operation at materially reduced capacity will have to be handled as remarks, giving capacity loss and dates. Remarks should be written on the reverse side of the form sheet.

Transferable Outage. Occasionally, on systems having a temporary superabundance of reserve capacity, units may have been out during the peak hours of weekdays for work which if the reserve had been normal could and would have been transferred and *confined* to off-peak hours of the day or to a nearby weekend or holiday period. These outages are classed as transferable. Evidently this classification is applicable only to 1-, 2- or at most 3-day outages that occurred on weekdays.

Scheduled Outage. A scheduled outage is one widely controllable as to time of occurrence so that it might have been or was postponed from one season to another, or even to another year. Such outages will usually have been planned months in advance. Annual overhaul is a typical scheduled outage. Scheduled outages are further classified as due to the unit (turbogenerator, condenser, and own auxiliaries); or as due to other cause such as: boiler, station or system rearrangement; or reconstruction of a unit to increase capacity, change frequency, and so forth as contrasted with reconstruction because of an excessive failure rate.

Forced Outage. All reported outages other than transferable or scheduled outages are classed as forced outages. Typically a forced outage is one due to causes requiring that the unit be taken out of service at once or within a few weeks, excepting transferable outages. Outages on weekends and holidays will be given separate treatment in the analysis of the returns; so that forced outages which were postponed to such days should be reported in the same way as any others. Forced outages are further classified as due to the unit (turbogenerator, condenser, and own auxiliaries) or as due to other causes such as boiler or transmission line unavailability, flood, bus failure, and so forth.

Combined Forced and Scheduled Outage. In certain cases of long forced outage the opportunity may have been utilized to schedule necessary overhaul work at the same time. The total duration of the outage may then have been determined by the overhaul. Since the primary interest of this questionnaire is forced outage, it is requested that in such cases the approximate outage time which would have been required without the overhaul be marked as forced outage and the remainder as scheduled outage.

Days Operated. If on any given day a unit was in service, that is, actually operated with switches closed to station bus for any length of time, however short, one full day of operation should be counted, unless a reported outage as defined above occurred on the same day.

Days Not Installed. Days prior to initial operation or following retirement of a unit should be marked days not installed. Days on which the generator was left uncoupled for operation as a synchronous condenser should also be marked days not installed.

Days Available But Not Operated. Obviously the days remaining after identifying outage days, days operated, and days not installed are days available, but not operated.

Treatment of Compound Units. In the case of 3-element cross-compound units; if the elements are regularly arranged so that the unit can be operated with any one element out, the elements should be reported as separate units.

Appendix II. Graphic Questionnaire. System Summary—Daily Record of Steam Boiler Operation and Outage[*]

Boiler Subcommittee, Prime Movers Committee of Edison Electric Institute

Boiler Unit. The boiler unit will be considered to include all components, fittings, piping, ducts and auxiliaries except those used or designed to be used in common with other boilers. Only boilers large enough to be important in fixing reserve requirements are included, the minimum size being set at 200,000 pounds per hour.

Reported Outages. In the analysis of reserve problems it is evident that only outages which reduce the margin between the daily peak load and the installed capacity need be considered. Thus in general any outage, regardless of length, which existed or occurred during the peak load portion of the

---

[*] Appendix I is a portion of the Explanatory Notes which accompanied the questionnaire sent to the reporting companies.

[*] Appendix II is a portion of the Explanatory Notes which accompanied the questionnaire sent to reporting companies.

day should be counted as one full day of outage, while an outage which was confined to off-peak hours of the day should be disregarded. Unavailability of turbines or load for the boiler does not constitute a boiler outage. Cases of successive nonoverlapping outages on the same day will have to be covered by remarks on the reverse side of the sheet. Outage days should be classified as described below.

Partial Outage. Where outage of some component, such as a mill or a fan, results in reducing capacity by a major fraction, as one half or one third, that outage should be reported as a fractional capacity outage in the manner indicated on the form. Cases in which boilers either after or in anticipation of failure were repaired or altered for temporary operation at materially reduced capacity also should be reported as partial outages.

Overhaul Outage. An overhaul outage is one widely controllable as to time of occurrence so that if desired it might have been or was avoided during the peak load season of the year. Such outages will generally have been scheduled months in advance. Overhaul outages are further classified as due to unit, for example, for renewal or repair of components or for correction of defects of the boiler itself or of its own auxiliaries; or as due to other cause, such as station rearrangement or alteration to increase capacity or to change the type of combustion equipment, and so forth.

Maintenance Outage. A maintenance outage is one which cannot be postponed from one season to another, but which can be assigned in advance so as to maintain an even or a minimum amount of simultaneous outage, or to utilize weekend time. Maintenance outages are further classified as due to unit or to other cause. A typical maintenance outage due to unit might be renewal of stoker parts or of furnace refractory in anticipation of failure; while one due to other cause might be replacement of a steam header valve beyond the boiler stop valve.

Emergency Outage. All reported outages other than overhaul or maintenance outages are classed as emergency outages, including in particular all cases which require a boiler to be taken out within a few hours and also those unforeseen outages of long duration which had not been regularly provided for in the normal maintenance schedule. Emergency outages are further classified as due to unit or to other cause. A typical emergency outage due to unit might be a tube rupture or the failure of the fan drive. An emergency outage due to other cause might result from failure of feedwater or coal supply.

Combined Emergency and Overhaul Outage. In certain cases of long emergency outage the opportunity may have been utilized to schedule necessary overhaul work at the same time. The total duration of the outage may then have been determined by the overhaul. Since the primary interest of this questionnaire is emergency outage, it is requested that in such cases the approximate outage time which would have been required without the overhaul be marked as emergency outage and the remainder as overhaul outage.

Days Operated. If on any given day a boiler was burning fuel for any length of time, however short and whether banked or steaming, one full day of operation should be counted unless a reported outage as defined above occurred on the same day.

Days Not Installed. Days prior to initial operation or following retirement of a boiler should be marked days not installed.

Days Available. Obviously the days remaining after identifying outage days, days operated, and days not installed, are days available but not operated. Days available will include days laid up.

Appendix III. Questionnaire on Hydroelectric Units—Forced Outages Chargeable to Units*

HYDRAULIC POWER COMMITTEE,
EDISON ELECTRIC INSTITUTE

An outage, to be classed as a forced outage, should be one resulting from the failure of the turbine, generator or any of their auxiliaries or pertinent structures extending from the water passages to the generator leads that requires that the unit be taken out of service. If the unit were taken out of service but could have been continued in operation had it been needed, without endangering life or property, until off-peak night hours, a weekend, or a longer previously scheduled normal maintenance period for that or some other unit for which it might have been substituted, and then have been repaired and returned to service during such period, the outage should not be classed as a forced outage.

It is recognized that, in some cases, the answers given will require considerable judgment as to what might have been done had some conditions been different from those actually experienced. If after due consideration doubt remains regarding the classification, the outage should be considered as forced.

If the outage were extended to permit work to be done on the unit other than the repair of the trouble that caused the forced outage or were extended simply because there was no immediate need for the unit to be returned to service, a reasonable estimate should be made of the minimum time that would have been required to return it to service had it actually been needed.

The primary purpose of this study is the consideration of the availability of hydroelectric units for capacity requirements. The critical hours for capacity for most systems, meaning the whole integrated interconnected system of which the hydro plant may be a part, is usually the heavy daily-load period extending from about 7 or 8 a.m. to about 10 or 11 p.m. on weekdays, which are commonly referred to as the peak hours.

An outage to be considered not forced must satisfy either one of the following conditions:

1. It is not necessary to immediately take the unit out of service and the eventual outage can be (or could have been) deferred to off-peak night hours, deferred to a weekend, or deferred for several months to a longer normally scheduled maintenance period for the unit taken out or some other unit for which it might be substituted in the normal maintenance schedule. The outage must be concluded and the unit restored to service before the next following heavy-load period or the end of the scheduled maintenance period, except that several such periods may be required and used provided the unit is available for service in the interim heavy-load periods.

2. It is necessary to immediately take the unit out of service but the outage occurs during off-peak night hours or a weekend. In such cases the outage must be concluded and the unit restored to service before the next following heavy-load period, even though further outage is required under the conditions specified in item (1) above.

Conversely, an outage to be considered forced must satisfy one of the following conditions:

3. It is not necessary to immediately take the unit out of service but the eventual outage cannot be taken care of during off-peak night hours, a weekend or normally scheduled maintenance period as described in item (1) above.

4. It is necessary to immediately take the unit out of service during the heavy load hours of a weekday.

5. It is necessary to immediately take the unit out of service during off-peak night hours or a weekend, but the outage cannot be concluded and the unit restored to service before the next following heavy load period.

Since the primary purpose of this study is the consideration of the availability of generating capacity, we must ask about each case whether the outage would have been taken immediately or would have been deferred had the unit at the time been needed for capacity purposes. The actual or possible need of a unit for energy generation, either firm or secondary, at the time of an outage has no influence on its classification as forced or not forced.

For example, a run of river plant with eight units may during a period of low flow be operating not more than four or five units during the heavy load hours of the day. An accident occurs which requires that one of the operating units be immediately shut down.

Such an outage is forced as defined under (4) above. Such an outage, however, would not be in demand were it possible to substitute one of the idle units for the one forced out.

Under the same situation as above, except that the unit could have been continued in service but was not simply because other units were available, the outage may or may not be forced. Its classification then depends on the necessary duration of the outage and would be covered by conditions (1) or (3).

In the same plant during high or sufficient flow all units may be in demand continuously. Nevertheless, outages may or may not be forced depending on the circumstances as they actually existed or would have existed had the units been needed for capacity rather than energy generation.

The same considerations apply to storage as well as run of river plants and to high and low flow equally well. The more familiar classification of in demand and not in demand are not related to the classifications forced and not forced. The tests outlined in (1) to (5) should cover all possible conditions which have bearing on the classification desired.

No Discussion

A 3,000-Horsepower Gas Turbine Power Plant

J. S. HAVERSTICK
ASSOCIATE AIEE

OVER THE past few years, several papers have been presented describing the gas turbine power plants with which the various manufacturers of turbines are working. The present paper describes a plant having somewhat different features than those described previously, and also presents performance characteristics of the plant which it is believed will be of value to those who must study and plan for the eventual use of gas turbine power.

Inasmuch as the compressor is a vital component of a gas turbine plant, much discussion has taken place concerning the relative merits of axial-flow and centrifugal machines; those who favor the axial-flow compressor usually claim a higher efficiency and less bulk, and those who favor the centrifugal compressor usually point to the broader range of operation and also indicate they believe that, with sufficient development, the efficiency of the centrifugal can be made to equal that of the axial. Herein, the compressor is a mixed-flow type which is adaptable to high-speed operation and, during its relatively short period of development, has proved that it is capable of high efficiency; its range of operation lies between those of the axial and centrifugal types.

A second distinguishing feature of the plant described herein is that the power output shaft is mechanically independent of the rotor of the compressor and compressor driving turbine. Such an arrangement is usually known as a split turbine design. It has the advantage of allowing the load to remain at constant speed while the compressor and its turbine are brought to their most desirable speed.

To allow even greater flexibility in the operation of the plant, a by-pass is placed around the power output turbine. It is only economical to use the by-pass during idling operation, but, on the other hand, its presence means that the plant may be used in applications where the simpler single-turbine plant is wholly unsuitable.

The cycle on which the design is based is the open cycle without intercooling of the compressor, regeneration, or reheating between turbines. It is accomplished by series flow through the compressor, combustors, high-pressure turbine, and power output turbine. All components are arranged along a common axis.

Design point conditions were chosen to be an ambient air temperature of 68 Fahrenheit degrees, a barometric pressure of 14.7 pounds per square inch, an over-all pressure ratio of 6 to 1, and a turbine inlet temperature of 1,300 Fahrenheit degrees with an output of 3,000 brake horsepower.

The general arrangement of the plant is shown in Figure 1 in which may be seen, starting at the left, the auxiliary housing, the compressor, the combustors, the high-pressure turbine, and the power turbine. All components other than the power turbine are in reality a power-gas generator, needed to produce the hot, compressed gases for the power turbine.

The compressor consists of three mixed-flow stages and is designed to deliver 44,500 cubic feet per minute at design air conditions when operating at 7,900 rpm. Each of the three impellers is made from forgings out of which the vanes and hub are machined to form an integral piece. Air enters the compressor radially and is turned immediately for axial entry into the first impeller. On being discharged from the rotor, the air enters a vaned diffuser which directs it radially outward. Following the diffusion it is brought back radially into the second stage, where the process is repeated. The casing and internal stator parts are all split on the horizontal center line for ease in handling during assembly and inspection. The rotor is supported at each end in sleeve-type journal bearings and is positioned axially by means of a Kingsbury-type thrust bearing. Labyrinth-type seals are used throughout, those between the suction of the first-stage impeller and the auxiliary housing being supplied with sealing air to insure that lubricating oil is not drawn into the main air stream.

The high-pressure turbine in this type plant is used primarily to drive the compressor, although, in addition, it drives the auxiliaries and may be adapted to supply a small amount of power for other services independent of the main power output. This machine is of the axial-flow type; it contains five stages, the rotating blades of each stage being attached to the rotor by fir-tree-type shanks fitted into corresponding slots

Figure 1. Gas turbine power plant

machined axially in the rotor. The complete rotor is carried in two sleeve-type journal bearings located at each end; the axial position is determined by the compressor thrust bearing, the thrust being transmitted through to the compressor rotor. The casing is split on the horizontal center line as with the compressor.

The power turbine is of the same general design as the high-pressure turbine, but it contains only three stages and includes its own Kingsbury-type thrust bearing. It is designed to develop 3,000 brake horsepower at 4,200 rpm with the compressor set operating under its design conditions, and, of course, with the bypass valves fully closed.

In order to keep the machines symmetrical about the axis and thus maintain control of thermal expansions, the by-pass, from between the turbines to the exhaust, completely surrounds the power turbine and contains several valves equally spaced.

The combustors are set in a circle concentric with the axis of rotation; eight are used, and each consists of conical liners arranged to gradually mix the secondary air with the combustion products.

The arrangement of the auxiliary housing is shown in diagrammatic form in Figure 2. Included are a tachometer, a main lubricating-oil pump, an auxiliary lubricating-oil pump, a fuel-oil pump, an overspeed trip, a low lubricating-oil pressure trip, and the free-wheeling clutches for the starting motor and turning motor, as well as the speed governor. The turning motor serves as the motor for the auxiliary oil pump to insure that, as the plant is cooling off, the heat conducted to the bearings will be carried away by the flow of oil. Since the free-wheeling clutches are fully automatic and cannot transmit torque in the reverse direction, the turning motor and starting motor may be brought into operation at any time.

Dimensions of the plant as a whole are given by the maximum diameter of the casing (68 inches), and by the length from power output coupling to starting motor coupling (22 feet, 8 inches).

As shown in Figure 3, the performance of the plant may be shown on a single plot, provided, of course, that the by-pass valves are kept closed. Figure 3 was prepared for the plant performance with design ambient conditions of temperature and pressure, and can be used directly only when such conditions prevail.

Inasmuch as design ambient conditions are rarely encountered, it is usually necessary to correct existing conditions back to standard. The correction factors necessary for this purpose are given in the figure as factors of each variable.

It is interesting to note that, in a plant such as this one with a separate power turbine, constant speed for the output is attained by reducing not only the maximum temperature but also the speed of the compressor set. The consequent reduction of centrifugal stress in the highest temperature region should then contribute to longer life for these members of the turbine.

Corresponding to the constant speed line for 3,600 rpm in Figure 3, the fuel rate curve is plotted separately in Figure 4. It is based on fuel oil having a higher heating value of 18,500 Btu per pound.

Figures 3 and 4 are limited in that they do not carry on down to idling conditions; therefore, to illustrate performance in this range, Figure 5 is presented. It is to be noted that, as the compressor-set speed is reduced by reducing the quantity of fuel, the inlet temperature to the high-pressure turbine falls to a minimum value and then rises again with subsequent reduction of fuel. The temperature rise must, of course, be kept within safe limits; there is a point, therefore, below which it is necessary to shut off the fuel completely, and so shut down the plant or supply outside power from the starting

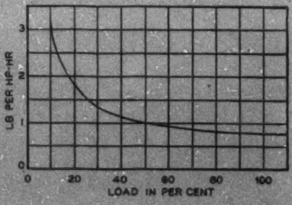

Figure 4. Fuel rate versus output at 3,600 rpm

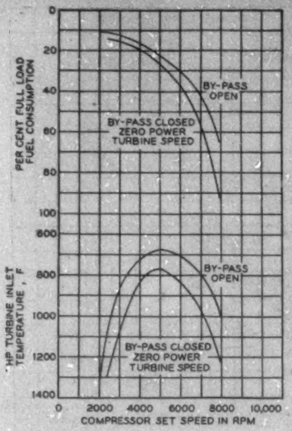

Figure 5. Idling conditions

motor if the compressor set is to remain in operation.

The amount by which the by-pass is opened affects the idling performance, since it is a means for lowering the exhaust pressure of the high-pressure turbine. As is apparent from the curves, it becomes worth while to open the valves during a prolonged period in which the plant is to be kept idling, thereby reducing the fuel consumption.

Another item of interest is the amount by which the high pressure turbine inlet temperature must be reduced to maintain constant speed in the compressor set as the by-pass is opened. As may be seen in Figure 6, the lowering of the pressure between the turbines requires, at full speed of the compressor set, a reduction of about 300 degrees Fahrenheit, and the reduction decreases rapidly as the compressor-set speed is reduced.

Had it been found that manipulation of the by-pass valves caused very large temperature changes, provision would have been necessary to hold the pressure between the turbines constant. This would mean the addition of valves to shut off flow to the power turbine as the by-pass valves were opened. The lack of these shut-off valves not only reduces mechanical complication, but, by allowing flow through the power turbine, maintains its temperature even at a standstill.

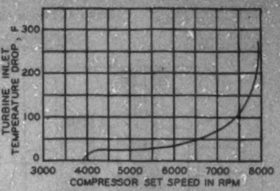

Figure 6. Turbine inlet temperature drop versus compressor speed from fully-closed to fully-open by-pass

The manner in which the plant is controlled is dependent, of course, upon the requirements of the driven load, but may in general be said to be speed control from the power turbine to the fuel supply, with a maximum temperature-limiting device as a safeguard for the high-pressure turbine.

Since it is not the purpose of this paper to discuss the possible applications for this type of power plant, details of the controls that might be used in different cases are omitted, but in conclusion, it may be pointed out that, since flexibility in operation is a main objective, many arrangements are possible.

No Discussion

Two Gas Turbines for Power Generation and Other Applications

ALAN HOWARD
MEMBER AIEE

Synopsis: This short paper, written as part of a symposium, outlines the status of a gas turbine development, briefly describes the two types of power plant resulting from this development to date, and outlines their applications.

THE GAS turbine, as in the case of most prime movers, has had a rather long history. It is, however, a new prime mover in being reduced to a form suitable for practical applications. A gas turbine may take a great many forms; throughout the world many designs are built and are in operation, and many more are underway. These range from the simplest type to very complex cycles which may involve both reciprocating and rotating equipment. These various types each have their attractive features and may fit particular applications to particular advantage.

Much has been written concerning the broad field available to the gas turbine as its development progresses. It does seem to be a type of power plant which will prove to be of wide usefulness. The gas turbine should prove its adaptability in two ways. First, even the simplest type of plant is, we believe, attractive for many applications without changing the basic unit. Second, as the over-all development progresses, further new types should become available with their own particular fields of superiority.

One important aspect of the gas turbine which is sometimes partly lost from sight among the glowing predictions for its future, is the fact that there is so far very little experience with it for general power purposes. Aside from process units designed for low temperatures, no really extensive operating experience has been reported anywhere.

During the war, two aircraft gas turbines of the axial flow type were developed by the General Electric Company at Schenectady, N. Y. These are shown in Figures 1 and 2. The *TG-100* has had many flights up to high altitude and has given a very good account of itself. The *TG-180*, and its successor the *TG-190*, are being used in a majority of the new jet

Paper 49-114, recommended by the AIEE power generation committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted November 17, 1948; made available for printing January 4, 1949.

Alan Howard is division engineer, gas turbine engineering division of the General Electric Company, Schenectady, N. Y.

Figure 5. Arrangement for test of 4,800-horsepower gas turbine for locomotive drive

fighters and bombers of the Air Force. Each of these is of the simplest type with one turbine, one compressor, and no intercooling or regeneration.

Based on this experience, but recognizing the difference in requirements for nonflying applications, a simple power plant with a design rating of 4,800 horsepower (at 1,500 feet altitude) has been designed, built, and tested in Schenectady. This power plant was designed particularly for locomotive applications, but with recognition that it should be attractive for many other types of installation also. Figures 3 and 4 show a cross-section and an external view respectively. The unit is approximately 19 feet long and weighs about five pounds per horsepower. Figure 5 shows the unit on test in Schenectady where it drove four d-c generators of the traction type through gearing. The tests and unit have been described in detail.[1,2] In summary, the power plant proved to more than meet its design rating and to be a little better in efficiency than the design predictions of 17 per cent based on net shaft power and the lower heating value of the fuel. Somewhat over 700 hours of operation have been accumulated. Some difficulties, of course, were encountered, but these were not of a basic nature.[2] Simple corrective measures were taken, and the over-all operation is considered very definitely encouraging. A majority of the running was on *Bunker C* (number 6) fuel oil, and a total of more than 230,000 gallons of this low-grade fuel has been burned.

The characteristics of this plant, based on the tests, are shown in Figures 6 and 7, while Figure 8 shows the effect of altitude. It will be seen that there is a definite effect of ambient temperature and of altitude. In these characteristics, the gas turbine is different from either steam plants or diesel engines; its features should be evaluated for each application. In cold weather, the power output obtainable increases substantially, whereas, in hot weather, the output falls off with exhaust temperature maintained constant. In dry locations, evaporative cooling of the inlet may be quite attractive since the wet-bulb temperature always may be attained. This will require on the general order of 1,500 to 2,000 pounds of water evaporated per hour. In at least one application, the incoming air will be cooled by a surface cooler.[3]

The exhaust temperature of the turbine varies with load and with ambient temperature, and the air flow also varies. This results in a variation of the heat available in the exhaust, as shown in Figure 7. This basic natural characteristic can be modified by the combustion of additional fuel in the exhaust gases prior to entering the waste heat boiler, or by throttling on the compressor inlet or

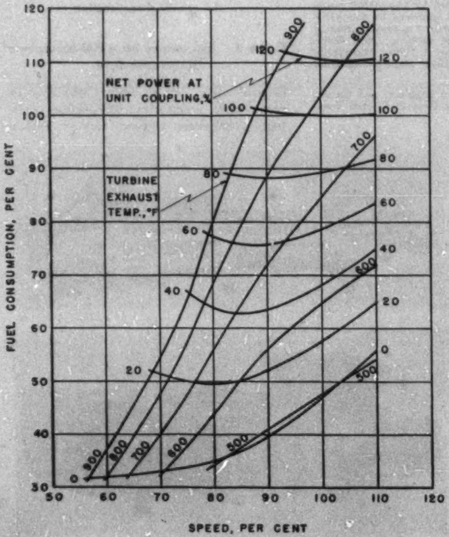

Figure 6. Tested thermal performance of a 4,800-horsepower gas-turbine power plant

100 per cent values correspond to 75,600,000 Btu/hour (based on the lower heating value), 6,700 rpm and 5,000 horsepower at sea level and 80 degrees Fahrenheit ambient

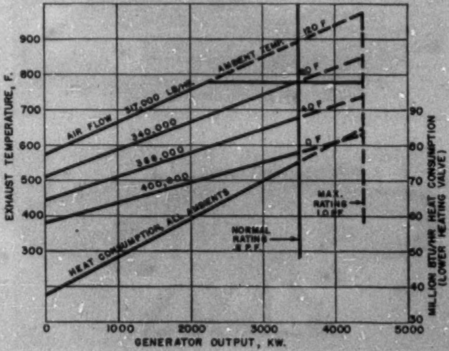

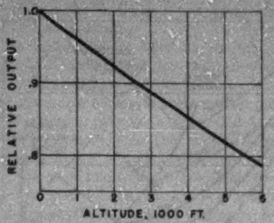

Figure 8. Effect of altitude on output and air flow

turbine discharge to raise the exhaust temperature at a given load. Of course, in doing this, the turbine exhaust temperature cannot be raised above the maximum permissible value. These possibilities of using waste heat are more fully covered elsewhere.[4]

Based on this successful operation, the power plant has been installed in a locomotive and is undergoing preliminary track tests as this is written. Furthermore, two of these power plants have been sold to public utilities for power generation purposes. In one of these applications, natural gas will be the fuel, and the exhaust will be used to heat the feed water of the existing steam power station in which the unit will be located. This application, which has been described in the technical press,[3] illustrates one of the adaptable features of this unit. An outline of the power plant, when used for power generation, is shown in Figure 9.

With this simple type of plant, the over-all efficiency is of a moderate value which indicates that the major application is expected to be where fuel is inexpensive, where the utilization of the waste heat is desirable, or where small size and light weight are important.

This type power plant requires cooling water only for lubricating oil, and even this can be dispensed with by the use of air-cooled radiators, if desired, so that the unit is particularly attractive where cooling water is difficult to obtain.

Since the power plant is relatively small, compact, and light in weight, simple, inexpensive foundations and housing are required, thus resulting in economical installations.

An attractive possibility for this simple unit is as a portable power plant, of which a preliminary outline is shown in Figure 10. While the details of this have not been developed fully, it appears likely that the generating plant could be put on one flat car with the fuel oil brought up in tank cars. Similar portable power plants well might form emergency units for pipe-line pumping spares, and probably could be transported in one or two trucks.

Other attractive applications for this plant should be in industrial power, gas or oil pipe-line pumping, and where the exhaust heat may be used directly, as in the drying of lumber.

For many applications, particularly the usual power generation case, a higher efficiency, both at full load and at part

load, than can be obtained with the simple cycle is desirable. Such increases in efficiency are obtained in the gas turbine primarily by using heat transfer elements in the form of intercoolers between stages of compression and regenerators making use of the turbine exhaust heat to preheat the air entering the combustion chambers. Figure 11 is a diagram of such a power-plant cycle, including temperatures and pressures at the various points in the cycle under the design conditions of 1,500 feet and 80 degrees Fahrenheit. Figure 12 is a perspective drawing of the physical appearance of such a plant, while Figures 13 and 14 show an approximate cross-section of the machinery and an installation outline. It will be noted that both the regenerator and intercooler consist of two units in parallel, and that the entire power plant is contained in a space approximately 50 feet long by 28 feet wide by 13 feet high. The total weight is expected to be around 60 pounds per kilowatt.

The turbine and compressor are divided into high and low pressure elements primarily to provide improved heat rate at reduced loads. At part load the low-pressure turbine and compressor will run at reduced speed, thus maintaining better cycle efficiency.

This power plant is now under construction, and the first of its type is ex-

pected to be in factory test operation within a few months.

It is designed for 5,000-kw generator-terminal output, and has an expected thermal efficiency of 28 per cent based on the generator terminal output and on the lower heating value of the fuel. This is a better efficiency than that attained by steam stations of comparable size.

The mechanical design has been described in detail in a recent paper,[5] which also gave the anticipated performance characteristics as shown in Figure 15. From this figure, it will be seen that the normal rating of the power plant is affected by ambient temperature as in the case of the simple type of power plant, but at a lesser rate. It is basically affected by altitude as shown in Figure 8, which applies approximately to any gas turbine. Relative to the normal rating, the maximum expected net output is about 15 per cent greater, which means that the full 5,000-kw net output should be maintained up to about 110 degrees Fahrenheit ambient. The part-load heat rate is higher than that at full load, but increases relatively slowly as load is reduced, so that at half power the heat rate should be only about 16 per cent higher than at full power.

This power plant requires relatively very little cooling water compared to a steam station of a similar rating. Normally, a total water flow, including intercoolers, oil coolers, and generator air coolers, of approximately 1,200 gallons per minute would be required. This is compared with around three to five times this value for a steam station. In addition to the good thermal efficiency and low cooling water requirements, this power plant is expected to have a relatively low installation cost. The version shown is essentially a one level plant with only the oil tank required to be below floor level.

In the perspective drawing, Figure 12, the exhaust openings from the regenerators are shown facing upward, and, in this case, the required exhaust ducting would be attached at these points and led in the most convenient manner to the outside. Alternatively, these regenerator outlets may be turned outward to each side or downward, if more convenient. Similarly, the inlet duct to the low-pressure compressor can be either along the floor or overhead. In common with the ducts for the 3,500-kw simple-cycle unit, these ducts normally would include simple sound absorbing means to suppress the high-frequency turbine and compressor noise. If desired, the regenerators can be left out and the turbine exhaust heat can be used for making steam or for other purposes, rather than preheating the combustion air. In this case the fuel rate would be increased by about one-third.

It is expected that these plants should be attractive for end-of-line installations, and for standby and peak-load operation where the quick starting feature would be of particular advantage. It is expected that completely automatic operation will be quite feasible.

As in the case of the 3,500-kw unit, this 5,000-kw plant is designed to be adaptable to the burning of a light or heavy fuel oil, including *Bunker C*, and to the combustion of gas. At the present time, three of these units have been ordered for installation in power stations; two of them will burn natural gas, while the other will burn *Bunker C* fuel.

In summary, a large-scale gas turbine developmental program is under way, including many component developments not outlined here. This development has resulted, so far, in the construction and test of the simple-cycle locomotive-type plant, the design and current construction of the high-efficiency 5,000-kw unit, the receipt of orders for both types for power generation, and the installation of the locomotive unit in a locomotive with preliminary track tests under way as this is written. This is all undertaken in the belief that the gas turbine will find wide use. However, it is not believed that it will displace in the near future other forms of prime mover, such as large steam turbines.

In this paper prepared for the symposium, a full description of these two power plants and their possibilities has not been attempted. It is hoped, however, that sufficient of the possibilities have been outlined to indicate the wide field to which we believe the present units are adaptable, and to indicate the general present state of development. It is anticipated that in the future other sizes and types of gas turbine will become available, and that experience with the present plants will prove them to have low maintenance and to be reliable and economical when properly applied. It is anticipated that, as developments progress, it will be possible to use coal as a fuel for gas turbines. This should considerably extend their field of usefulness.

Discussion

W. A. Wilson (Elliott Company, Jeanette, Pa.): The papers presented at the gas turbine symposium provide an exceptionally comprehensive view of current gas-turbine development in this country. In doing this they indicate a diversity of solutions of similar problems which may seem surprising or even alarming. This is a consequence of one source of the virility of the gas-turbine idea, that is, its extreme flexibility. The gas-turbine designer is "embarrassed with riches" when it comes to the number of degrees of freedom allowable in making his technical choices.

This is true not only with respect to mechanical design but, even more fundamentally, with respect to the choice of the thermodynamic processes to be employed. It is one of the most appealing virtues of the gas turbine that it is adaptable to the implementation of a whole range of cycles. Since none of these cycles has a clean-cut superiority on all counts, the choice between them is far from easy. Some insight into the reasons for the several selections indicated by the papers may be given by a brief exposition of the three "basic" gas-turbine cycles.

The simple gas turbine operates on the Brayton cycle—adiabatic compression, constant-pressure heat addition, adiabatic expansion. Theoretically, the efficiency of this cycle increases indefinitely with pressure ratio. At the same time, the ratio of useful output to turbine (and compressor) power decreases drastically. This latter circumstance makes the high-pressure-ratio simple-cycle extremely sensitive to component efficiencies. Simple-cycle gas turbines operating near 1300 degrees Fahrenheit usually are designed for operation at a pressure ratio of five or thereabouts. For this condition the output per pound of air handled is a maximum. A few more points of efficiency can be squeezed out by a considerable increase in pressure ratio, but at a less favorable air rate and by using more expensive compressors and turbines.

The introduction of a regenerator into the Brayton cycle creates the second basic gas-turbine process. This modification has more profound thermodynamic significance than usually is recognized. The ideal cycle—assuming complete recovery of available exhaust heat—has a maximum efficiency at unity pressure ratio equivalent to that of the Carnot cycle; instead of continually increasing as pressure ratio is raised, it declines. Actual gas turbines employing the Brayton cycle with practical degrees of regeneration have peak efficiencies at relatively low pressure ratios—approximately 5.0 for a 1300 degree Fahrenheit, 50 per cent regeneration plant. Since this corresponds reasonably closely to the optimum condition relative to air rate, the selection of a design pressure ratio is more straightforward than in the case of the non-regenerative plant.

The ultimate in ideal gas turbine processes is the Erricson full-regenerative cycle—isothermal compression, constant-pressure heating, isothermal expansion, constant-pressure cooling. The theoretical efficiency of this cycle is independent of pressure ratio, being everywhere equal to the Carnot efficiency. Compound cycles incorporating inter-cooling, reheat, and regeneration may be regarded as efforts to approximate this ideal. The independence of ideal cycle efficiency from pressure ratio is reflected in the flat performance curves of typical compound cycles. These more complicated plants pay off in other respects also: efficiencies are brought to high levels; output per pound of air may be double that for simple cycles; part load performance may be excellent, and at all loads is relatively insensitive to deterioration of component efficiencies. These advantages are gained, of course, only at the expense of additional rotating and stationary apparatus, but up to half the turbine power developed is useful power instead of a little over one third, and, for a given percentage of heat recovery, between one-third and one-half as much heat transfer surface is required per unit of plant output. It seems safe to predict that, if the gas turbine is to become more than a special purpose prime mover, it must embody a compound cycle. The selection of a particular version will involve compromise, based on judgment developed from experience in such endeavors as have been described at the symposium.

There is considerable question in the writer's mind as to whether simple open-cycle plants can be justified for power generation in capacities as high as the 7,500 kw indicated in Tucker's conference paper. Certainly increasing this capacity to 15,000 kw by essentially duplicating the compressor and turbine elements will be difficult to justify. The superposition of smaller high-pressure compressor and turbine elements, and incorporation of intercooling and reheating will develop nearly the same increase in capacity and at the same time nearly double the efficiency.

Philip Sporn (American Gas and Electric Service Corporation, New York, N. Y.): The authors are to be commended for presenting a series of papers which give us an authoritative picture of the present status of the gas-turbine power plant for application to public utility systems. It is this kind of approach which ultimately will serve to fill the vacuum in our knowledge of the performance of the gas turbine in industrial or power applications based upon application and operating experience.

The application of the gas turbine to the end-of-the-line situations may offer potentialities on a number of public utility systems. It doubtless can be used on such systems where oil and gas are economically available and are the prevalent fuels. However, for general application, a coal-burning unit will be required. This is a development still to be completed. While no basic difficulties stand in the way, the technical difficulties still are formidable.

Once the coal problem is solved, it should be possible to develop more clearly the particular place of the gas turbine in a general power supply picture—something very difficult to do now. There can be no question that every progressive power-system engineer and executive will be alert to new developments in that field, and that he will grasp every economically sound opportunity to exploit the gas turbine as a new tool in building the power system of tomorrow on the most economical power-supply base possible.

One line of development seems fairly obvious. Following the pattern of steam-turbine development, it is only natural to expect that the development of the gas turbines will be in the direction of higher and higher operating temperatures. This will bring about a material improvement in the thermal performance of the gas turbine and improve its competitive position. It will contribute to better designs of steam turbines as alloy steels for higher temperatures are developed, and this will serve to check the competitive gain of the gas turbine. However, it is important to point out that this development will not obviate the need of research in the direction of producing a coal-burning gas turbine which is so essential if such a machine is going to have widespread application.

The point about the moving target presented by the modern steam turbine should not be lost sight of. If the coal-fired gas turbine were available today for large-scale power generation, the steam-power mark it would have to strive to match or beat is that which is now possible with a 2,000 pounds per square inch, 1,050–1,000 degree reheat cycle, which is typical of some six large installations now in progress on the American Gas and Electric Company system, and which are designed to generate power at 9,300 Btu per kilowatt-hour net generation. It would be unsound, however, to assume that steam power will remain at this level during the period of development of the gas turbine. I feel that the goal for gas turbines in large-scale power generation will be even higher, as indicated by performance of a 2,000-pound 1,200-degree Fahrenheit steam reheat cycle which should be capable of generating at approximately 8,700 Btu per net kilowatt-hour. This projected steam cycle, utilizing 1,200 degrees as the operating temperature, is substantially higher than any steam equipment on which we presently have experience. The lessons learned on gas turbines should be helpful in this development.

Gas Turbines in Stationary Power Generation

F. T. HAGUE
ASSOCIATE AIEE

THE ULTIMATE possibilities of gas turbines for many types of application have been publicized widely. There is no lack of understanding of thermodynamic principles to hold up development progress. So many of the possibilities, on which improved performance at an economic cost is dependent, are in such a preliminary stage of research that it is manifestly impossible to put a time schedule on their reduction to practice, or to predict now the extent to which these possibilities ultimately will be incorporated in commercial gas turbines. This very uncertainty makes the future of the gas turbine intriguing to engineers.

The gas turbine is an economic and practical reality in its present stage of development for many types of application. Its acceptance as a high-speed-aircraft power plant is well established. It is pre-eminent in this field for one general reason—it does a better job than any competitive power plant. Doing a better job means that the integration and evaluation of its characteristics, that is, first cost, size, cost of power generation, life, maintenance, and reliability, puts it in a more favorable position than any other type of plant. Gas turbines will compete with and will supersede other types of power plants only when they "do a better job" in an evaluated sense.

In the stationary power generation field, the gas-turbine plant and the steam plant may be compared on an economic basis by arbitrarily assuming that the life, maintenance, and reliability characteristics can be made equal, leaving first cost and cost of power generation as the predominant criteria. Such an economic analysis has been described by A. Mendahl,[1] resulting in a simple diagram which permits the determination of the plant load factor at which two plants, of different first cost, have the same cost per unit of power generated for any specific fuel costs. Such an analysis of steam and gas-turbine plants of current design indicates that the present-day gas turbine has economic application possibilities in the stationary power generation field whenever the price of fuel is sufficiently low or the load factor is less than ten per cent, and then only when the gas turbine plant first cost is relatively low.

This is a reasonably encouraging outlook for a new type of stationary power-generation plant. It indicates the two lines along which the gas turbine probably will be introduced into the power-generation field. It also serves to give a quantitative answer to the usual question of how much improvement in the gas turbine plant's "first cost versus power generating cost" relationship must be achieved, by further research and development, before the gas-turbine plant can challenge the steam plant as an economic base-load operating unit for any specific set of fuel cost conditions. It appears that the gas-turbine plant will serve initially the stationary power-generation field not by challenging the steam plant, but by supplementing it. The gas-turbine plant, at its present stage of development, has the peculiar characteristics to give it an aptitude for economic peak-load service that the steam plant cannot match.

All gas turbines for stationary power generation, built or being built in both the United States and Europe, have been characterized by:

1. The availability of very cheap fuel, such as cheap oil from pipe lines, or gas costing one-third as much per heat unit as coal at the mine mouth in Pennsylvania.
2. Low load factor.
3. Experimental large plants, in England and France, subsidized by their governments.

In addition, there always will be special cases. A gas-turbine generating plant has been installed in an English factory as insurance against a national coal shortage, and a gas-turbine plant has been justified in the United States by using its exhaust heat, under exceptionally favorable circumstances, to increase the output of another generating unit.

There are very few locations in the world that present the same attractive combination of low fuel cost and large, industrial, electric power consumption as the cities located near the southern oil and gas fields of the United States. The availability of gas at one-third to one-fifth the cost of coal makes this a most attractive territory for the economic installation of gas-turbine plants. Low fuel costs permit the use of simple plants that are very desirable as initial installations of a new type of plant. Announcements have been made of three small gas-turbine generating units to be installed in this territory.

In Great Britain there is no cheap fuel. This condition favors the complicated type of gas-turbine plant where every effort is expended to attain low heat consumption per unit of power generated. This efficient and high-cost type of plant, using high-cost liquid fuel, is not economic at present cost levels, except for applications having very low load factors. The British Ministry of Supply has contracts for 15,000-kw units to be installed near New Castle and Manchester, and a 12,500-kw Escher-Wyss-type closed-cycle unit near Glasgow. These units will be installed in existing power stations which supply power to the national grid in Great Britain. As experimental installations, these units may be operated or tested as their availability permits.

Paper 49-115, recommended by the AIEE power generation committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted November 16, 1948; made available for printing January 4, 1949.

F. T. Hague is a consulting engineer with the steam and aviation gas turbine divisions of the Westinghouse Electric Corporation, Lester, Pa.

The English objective is both domestic and export, and reflects the opinion that long range benefits will accrue to Great Britain through the development and patent control of all types of gas turbines. These installations have the primary objective of giving their manufacturers an opportunity to "get their hand in" by actually designing, manufacturing, and operating these rather large size units, in order to get first-hand experience with the problems involved. At this stage of gas-turbine development they believe that actual experience, through construction and operation, is more important to further progress than long term component research in laboratories that are not available in England at this time.

The pattern of gas-turbine development for power generation in France is quite similar to that in England. Electricitie de France is the nationalized instrument which is financing three installations. None of these is economic as base-load installations; all of them have been promoted to get first-hand operating experience. These installations are all for suburban Paris stations as follows:

1. A 2,000-kw open-cycle unit of conventional type.
2. A 15,000-kw combined steam and gas-turbine unit employing some 30 free-piston gas generators.
3. A 12,500-kw closed-cycle unit being built by Escher Wyss of Zurich, Switzerland.

These English and French plants are a government investment in gas-turbine development, for the purpose of providing test plants from which constructional and operating data can be obtained and coordinated, and without which no real progress in this field ultimately can be made. Our industrial firms would have to invest several million dollars in a development and construction program, without reasonable assurance of an economic market for the end product, to gain comparable experience to that which will flow from these government-subsidized programs.

It is an almost unanimous opinion, both here and abroad, that there remains much work in research and development before the gas turbine can be considered as a practical and economic power plant for base-load power generation in competition with coal-fired steam plants. It will be found very attractive as a peak-load plant. It must burn coal if it is to compete with coal-burning base-load steam plants. Its cycle efficiency increases three times as fast as in a steam plant for higher top temperatures, so that its future promise for lower cost power generation is tied up largely with material development and constructional problems to utilize temperatures 300 to 500 degrees Fahrenheit above present-day levels. The limited availability, at times of national emergency, of the rare elements essential to higher-temperature materials is being given consideration in this materials research.

Continuing development of the gas turbine's major components—compressors, combustors, and turbines—is being accelerated, in the gas-turbine aviation engine program, by the availability of government-sponsored component research laboratories. At the same time several manufacturers are acquiring essential practical experience, by making applications of gas turbine plants in those fields where it is now economic, thereby laying the groundwork to use important research developments as they become available.

The Use of Air-Core Reactors as Fault Limiting Means on High Interrupting Capacity Controllers

JOHN D. LEITCH
FELLOW AIEE

THE USE of air-core reactors as current limiting means is very old and well established. They are used in large power networks for the protection of generating equipment and the transmission system. Because of the large currents in such networks, the reactors have very small inductances to avoid excessive voltage drops and are made of large conductors to keep losses within reasonable values. The electromagnetic forces, experienced during a fault, demand very rigid construction, consequently they often are embedded in concrete. If, however, reactors are installed in feeder or branch circuits where the normal currents are of much lower values, their inductances can be increased proportionately, limiting fault currents to lower values.

For many years it has been the general practice to install motor controllers with moderate interrupting capacity (ten times their rating) in branch circuits without regard to the available fault kilovolt-amperes at the point of installation. It was considered adequate to provide protection for these and other branch circuits with a backup circuit breaker. In the event of a fault, the controller opens before the circuit breaker but often fails to clear the circuit, thus requiring operation of the circuit breaker, but not before considerable damage has been done. To overcome this, there recently has been an increase in the use of current-limiting fuses in conjunction with moderate interrupting capacity controllers. It is difficult to correlate such fuses and controllers so that the fuse clears the circuit on partial faults slightly above the interrupting capacity of the controller. This correlation is much easier when current-limiting fuses are used in conjunction with high-interrupting capacity controllers. In either case one or more fuses must be replaced after the interruption of a fault.

When air-core reactors are designed to limit fault currents below the interrupting ability of moderate interrupting capacity controllers, the required inductances are so high that the reactors become too large and costly and the voltage drops too great.

When the reactors are designed for use with high-interrupting capacity controllers (50,000 kva), the required inductances are very much less and this, combined with the smaller currents in the motor branch circuits, results in reactors of surprisingly small size and weight.

This paper deals with the design and application of air-core reactors for motor branch circuits in conjunction with high-interrupting capacity controllers. By selecting reactors capable of limiting a source of infinite power to 25,000 kva, much of the time-consuming calculation of system constants is eliminated. There are, however, two factors which limit the range of application of such air-core reactors. One is their increase in size and weight with increase in horsepower while the other is the reduction in voltage at the motor during starting. These limitations are discussed in detail.

In selecting circuit breakers for installation at various points in a power distribution system, it is customary to calculate, or in some way determine, the maximum available fault current at each point and to select circuit breakers having interrupting abilities in excess of these possible currents. Any subsequent increase in the available kilovolt-amperes necessitates a review of the system to determine the adequacy of the protection provided by existing circuit breakers.

Similar analysis is usually made prior to the selection of high-interrupting capacity controllers in motor branch circuits although calculations rarely go beyond the last bank of transformers. Having estimated that the maximum available fault might be 20,000 kva, it is customary to install starters having interrupting capacities of 25,000 or 50,000 kva depending upon the likelihood of increasing the available kilovolt-amperes at some future date. Frequently, however, the available kilovolt-amperes is increased beyond the interrupting capacity of the controller, necessitating a costly change.

By the introduction of adequate impedance in the branch circuit at the controller, the maximum fault can be limited to 25,000 kva. If, in addition, the controller itself has an interrupting capacity of 50,000 kva, adequate protection is provided in the circuit irrespective of any future increase in the available kilovolt-amperes of the system. If a particular feeder circuit supplies power to more than one motor, it might appear to be good practice to install one set of air-core reactors for the entire group of motors. Should additional motors be connected at some future time, new reactors would probably be required. By installing individual reactors for each motor, the reactors themselves are smaller and the installation is independent of future changes in feeder load.

In calculating the size and weight of many air-core reactors, it was surprising how small they actually are for application within an appreciable and important range of motor sizes. Before discussing the reactors themselves and their application limitations, it might prove worth-

Paper 49-117, recommended by the AIEE industrial control committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted November 15, 1948; made available for printing December 20, 1948.

John D. Leitch is chief engineer with the Electric Controller and Manufacturing Company, Cleveland, Ohio.

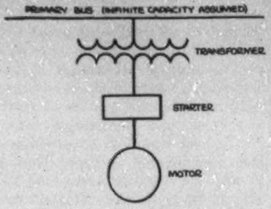

Figure 1. Motor feeder circuit

while to consider the characteristics of branch circuits.

Motor Circuits

When applying high-interrupting capacity controllers to motor circuits, it is customary to assume infinite available kilovolt-amperes at the primary of the feeder transformer, since the primary circuit impedance is usually low relative to that of the transformer itself and the motor lines. Figure 1 shows a typical motor circuit consisting of a transformer, a starter, and a motor. Other motors and starters may be on the same feeder, but need not be considered at present.

Assuming the transformer to have an impedance of 6 per cent, the maximum available kilovolt-amperes at its secondary terminals may be taken as its rated kilovolt-amperes divided by 0.06. The impedance of the transformer can be expressed as an equivalent secondary line reactance in equation 1.

$$\frac{E^2}{1{,}000X_L} = \text{maximum available kilovolt-amperes} \quad (1)$$

where E is the line to line open-circuit secondary voltage.

Table I lists the available kilovolt-amperes at the transformer secondary and the equivalent line reactance for a series of 6 per cent impedance transformers of different rated kilovolt-amperes having 2,300- and 4,600-volt secondaries.

The last four columns of Table I list the additional reactance per line necessary to reduce the available kilovolt-amperes to 25,000 and 50,000. For example, the equivalent line reactance of a 4,000-kva 6 per cent impedance transformer at 2,300 volts is 0.08 ohm, the reactance required to reduce infinite available kilovolt-amperes to 25,000 is 0.21 ohm, and the difference, 0.13 ohm, is the necessary additional reactance.

It is obvious that for transformers of lower rated kilovolt-amperes, there is no need for air-core reactors as a fault limiting means if controllers are used having interrupting abilities of 25,000 or 50,000 kva. The reactances of the lines themselves have been neglected, but if the lines are widely spaced and of considerable length they will reduce the available kilovolt-amperes at the motor. In applying air-core reactors as fault limiting means, it would be a waste of power and equipment to install them on a starter at the end of a long line.

Another impedance component between the transformer and the controller contacts is the overload relay. For a given design of magnetic overload relay, the coils are chosen according to the motor horsepower in such a way that the ampere-turns are essentially constant. This means that the number of turns varies inversely as the horsepower and the reactance varies inversely as the square of the horsepower. During a series of high-interrupting capacity tests, it was quite apparent that the overload relay coil impedance should not be neglected, especially at the lower horsepowers. Table II shows how the saturated impedance of an overload relay varies with the horsepower rating of its coil.

The saturated impedance of the 50-horsepower coil is about equal to that required per line to reduce infinite available kilovolt-amperes to 50,000 at 2,300 volts. It is therefore obvious that magnetic overload relays cannot be neglected on lower horsepower controllers and should be considered when applying fault limiting air-core reactors.

Table II. Saturated Impedance of Magnetic Overload Relay

Horsepower, 2,300 Volts	Turns	Saturated Impedance in Ohms (60 cycles)
25	120	0.361
50	65	0.104
100	34	0.028
300	12	0.0035
600	6	0.0009
1,200	3	0.0002

Table

Transformer Rating; Kva, 6 Per Cent Impedance	Available Kva at Transformer Secondary	Equivalent Line Reactance in Ohms		Additional Reactance Per Line Necessary to Reduce Available Kva			
				At 2,300 Volts		At 4,600 Volts	
		2,300 Volts	4,600 Volts	To 25,000	To 50,000	To 25,000	To 50,000
1,000	16,600	0.32	1.28	0	0	0	0
1,500	25,000	0.21	0.84	0	0	0	0

3,000	50,000	0.105	0.42	0.105	0	0.4	0
4,000	66,000	0.08	0.32	0.13	0.026	0.52	0.10
5,000	83,000	0.064	0.25	0.15	0.042	0.60	0.17
6,000	100,000	0.053	0.21	0.16	0.053	0.64	0.21
7,000	116,000	0.045	0.18	0.165	0.061	0.66	0.24
8,000	133,000	0.04	0.16	0.17	0.066	0.68	0.26
9,000	150,000	0.035	0.14	0.175	0.071	0.70	0.28
10,000	166,000	0.032	0.13	0.178	0.074	0.71	0.29
12,000	200,000	0.026	0.105	0.184	0.080	0.74	0.31

The possibility of designing magnetic overload relays which would at the same time serve as current-limiting reactors suggests itself. The conventional overload relay demands constant ampere-turns with variation in horsepower while the reactors demand constant inductance. In addition it is desirable that the power losses be constant over the horsepower range. Because of these limitations, the idea does not appear offhand to be economically practical.

Figure 2 shows graphically the reactance necessary to reduce any available kilovolt-amperes to 25,000 and 50,000 at 2,300 volts. These two curves differ in their ordinates by the constant amount 0.106 ohm, the reactance per line necessary to reduce 50,000 available kilovolt-amperes to 25,000. Referring to the ordinate for 200,000 available kilovolt-amperes, the amount of reactance required to reduce infinite available kilovolt-amperes to 200,000 is given by *BC* or *DE* on the two curves. This reactance (0.026 ohm) is only 14 per cent of that required (0.184 ohm) to reduce 200,000 available kilovolt-amperes to 25,000.

All the calculations so far have been based on steady-state fault currents. Actually the controller is called upon to interrupt currents of somewhat higher values because of the existence of transient d-c components. Under certain conditions if a short circuit is applied at the instant $E=0$, the current wave is displaced by an amount equal to the peak value of the steady-state wave. It can be shown easily that the total rms value of a completely displaced sine wave is equal to $\sqrt{3}$ times the rms value of the a-c wave alone. Actually the d-c component decays exponentially and disappears within a few cycles. If interruption occurs within the first half cycle (60 cycles per second), the total rms current interrupted might be as high as 1.5 times the rms value of the a-c component.

Should a completely displaced wave occur in one phase of a 3-phase system, the displacement in the other two phases will be half the a-c peak value and in the opposite direction since the sum of the d-c components is zero. This gives a total rms initial current of 1.23 times the rms value of the a-c wave and the average total rms initial currents for the three phases is 1.4 times the a-c rms current. A factor of 1.25 is often used in estimating the average of the total rms currents one half cycle after the fault, the difference between the 1.4 and 1.25 factors being an estimate of the decay of the d-c component during the first half cycle.

In applying current-limiting high-interrupting capacity fuses to motor feeder circuits, it is customary to multiply the available steady-state fault currents by 1.6 to obtain the total rms current that one of the three fuses may be called upon to interrupt during the first quarter cycle of a fault. In selecting circuit breakers for circuits having known available steady-state fault currents, the operating time of the circuit breaker is important, since the delay in opening is used along with the decrement characteristics of the circuit in determining the total rms current to be interrupted.

High-interrupting capacity controllers, which are not latched-in, start to part their contacts within a cycle of the instant of fault. Tests show the presence of total rms currents as high as 1.5 times the a-c component at the instant of interruption. Thus the interrupting capacity of the controller should be at least 50 per cent above the maximum available steady-state fault kilovolt-amperes. The present top rating of standard high-interrupting capacity controllers is 50,000 kva at 2,300 and 4,600 volts, based on the average of the phase currents including the d-c components. Therefore it was decided to use air-core reactors which would limit infinite available kilovolt-amperes to 25,000 steady state, thereby providing an additional factor of safety over that inherent in the controller.

Design and Application of Reactors

The reactance required to reduce any available kilovolt-amperes from one value to another is proportional to the square of the voltage, and the inductance corresponding to any reactance varies inversely as the frequency of the system. Table III lists the various inductances corresponding to the required reactances.

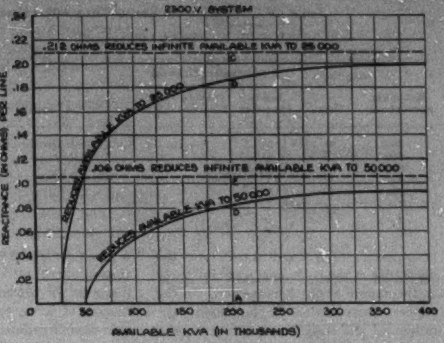

Figure 2. Reactance required to limit kilovolt-amperes to 25,000 and 50,000

Similar tables could be prepared for the inductances required to limit the available kilovolt-amperes to 50,000 and of course to extend the range in voltages and frequencies. This paper deals primarily with 2,300- and 4,600-volt systems, although comments will be made later regarding low-voltage systems. From an economic point of view, it is desirable to use a minimum number of reactors for a given range in motor sizes. By considering only infinite available kilovolt-amperes, the required number of reactors is reduced to a minimum and each installation is independent of the system constants and future changes in the available kilovolt-amperes.

Before a given reactor can be designed for a motor circuit of given horsepower, it is necessary to determine an acceptable power loss per coil at full load current. Heat tests were made in a controller enclosure, of approximately the anticipated size, to determine the temperature rise produced by various losses up to 200 watts per reactor. It was found that 100 watts per coil or 300 watts for a 3-phase controller gives a temperature rise less than 20 degrees centigrade and this was accepted as a reasonable power loss. In all of the design calculations which follow, this figure was used in determining the cross-section of the reactor winding.

The foregoing limitations can be used in conjunction with the well-known empirical formula[1]

$$L = \frac{aN^2}{238 \times 10^6} \text{ henries} \tag{2}$$

in designing air-core reactors. N is the number of turns and a is the radius of the mean turn in inches. This formula is very useful in making a rough estimate of the size of a given reactor and holds quite accurately where $a = 1.5b = 1.5c$, a, b, and c having the meanings shown in Figure 3.

A modification of the above formula is

$$L = aN^2 p \times 10^{-7} \text{ henries} \tag{3}$$

where the factor p is a function[2] of $b+c/2a$. This formula is useful where the above relationship between a, b, and c does not hold. There are other well-known empirical formulas,[3,4] of greater complexity which can be used where higher accuracy is required.

Using these formulas along with the power loss limitation, a series of air-core reactors was designed for 2,300-volt 60-cycle motors from 200 to 1,500 horsepower. The results of these calculations are listed in Table IV.

Table IV shows not only how rapidly the size of the reactor increases with horsepower, but how surprisingly small the reactors are for motors up to 600

Table III

Change in Available Kva From	To	Required Reactance 2,300 Volts	4,600 Volts	Required Inductance (in Millihenries) 2,300 Volts 60 Cycles	25 Cycles	4,600 Volts 60 Cycles	25 Cycles

Tab.e IV. Variation in Reactor Size with Horsepower

(0.56 Millihenry)

Maximum Horsepower	Turns	Dimensions (Inches) Inside Diameter	Outside Diameter	Width	Size of Copper	Resistance in Ohms at 25° C	Weight in Pounds
200	66	$3\frac{3}{4}$	$7\frac{1}{2}$	2	Number 5 square	0.0243	12.25
400	54	$5\frac{3}{4}$	$12\frac{3}{8}$	3	$\frac{3}{32}\times1\frac{3}{4}$	0.0087	56.5
600	54	$5\frac{3}{4}$	14	4	$\frac{1}{8}\times1\frac{3}{4}$	0.0050	114
1,000	38	12	$24\frac{3}{4}$	$6\frac{1}{4}$	$\frac{5}{16}\times2\frac{7}{8}$	0.00164	625
1,500	40	14	32	$11\frac{1}{2}$	$\frac{7}{16}\times5\frac{1}{8}$	0.0007	2,240

horsepower. For fixed watts loss, the resistance of the coils must vary inversely as the square of the horsepower. As the copper cross-section is increased, the radius of the mean turn increases and consequently the weight of the reactor increases faster than the square of the horsepower. Figure 4 shows graphically how the reactor weight varies with horsepower. It will be noted that the average gradient of this curve is quite low up to 600 horsepower and that thereafter it increases rapidly. This suggests placing an upper limit of about 600 horsepower on the application of air-core reactors on 2,300-volt 60-cycle systems. If this were the only reason for such a limitation, it might be acceptable to permit greater power loss per reactor for 1,000- and 1,500-horsepower motors. If, for example, the 600-horsepower reactor in Table IV were used with the 1,000-horsepower motor, the power loss would be increased to about 320 watts at full load current. Similarly if a new reactor were designed for the 1,500-horsepower motor allowing 400 watts loss per coil, its weight would be reduced to about 300 pounds. There is however another and more important limitation to the application of air-core reactors. This limitation will be discussed later.

It is desirable to use the same enclosure for all sizes of reactors within the range of a given controller. This places a limitation of about $14\frac{1}{2}$ inches on the outside diameter for the enclosure in mind. For reasons of economy in mounting, the inside diameter should be limited to one or two sizes. These conditions are met by the first three reactors on Table IV.

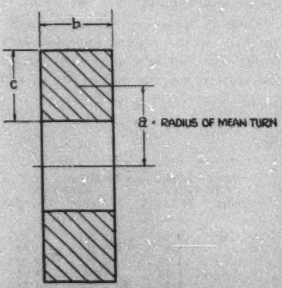

Figure 3. Cross section of reactor

If reactors are designed for various horsepowers at other voltages and frequencies, the same general results will be obtained. For 25-cycle systems, the inductances must be increased by the ratio 60/25 to obtain the same reactances, consequently the reactor size and weight will become quite large at about 300 horsepower.

For 4,600-volt 60-cycle systems, the reactors will have four times the inductances for 2,300-volt systems. For the same reactor dimensions, the reactance and resistance remain in the same ratio, consequently for the same power loss, the reactors again will become large at about 600 horsepower. Similarly 4,600-volt 25-cycle reactors will be limited to about 300 horsepower.

Table V lists eight reactors having weights less than 115 pounds and outside diameters less than $14\frac{1}{2}$ inches which may be applied to a wide range in motor sizes, a range which statistically represents more than 90 per cent of the total applications in this field.

Reactor 1, on Table V, weighs only $12\frac{1}{4}$ pounds. Obviously it would not be worthwhile considering additional reactors for motors lower than 200 horsepower. The power loss at full load current (50 amperes) is only 60 watts and of course will be less with smaller motors.

Had 50,000 been chosen instead of 25,000 as the limited kilovolt-amperes, the inductances required would have been halved and the maximum horsepower increased about 40 per cent. There is no reason why such a choice could not be made and the reactors used in conjunction with controllers or circuit breakers having interrupting capacities in excess of 50,000 kva. Such a procedure might be warranted for horsepowers above those listed in the last column of Table V.

Effect of Air-Core Reactors on Motor Voltages and Torque

It is important to know the effect of the air-core reactors on the motor torque during starting and running. Figure 5 shows the power circuit of a motor and controller with air-core reactors.

Assuming a star-connected motor and letting $\mathbf{Z}_m$ represent the equivalent impedance of each of the 3-phase windings at any motor speed, then

$$\mathbf{Z}_m=R_m+jX_m=\frac{E\underline{|0}}{\sqrt{3}I_m\underline{|-\theta}}$$
$$=\frac{E}{\sqrt{3}}\cdot\frac{\cos\theta+j\sin\theta}{I_m} \qquad (4)$$

where R_m and X_m are the equivalent resistance and reactance respectively of each of the windings and I_m is the current when the motor is connected directly to the line without reactors and θ is the angle of current lag behind the voltage.

When the air-core reactors are included, the total equivalent impedance per phase is given by

$$\mathbf{Z}_t=\mathbf{Z}_m+\mathbf{Z}_r=R_t+jX_t \qquad (5)$$

where $\mathbf{Z}_r$ is the reactor impedance. Neglecting the resistance of the reactors makes $R_t = R_m$ and

$$\mathbf{Z}_t=R_m+jX_t=\sqrt{R_m^2+(X_m+X_r)^2}\,\underline{|\theta_1} \qquad (6)$$

where

$$\theta_1=\tan^{-1}\left(\frac{X_m+X_r}{R_m}\right)$$

If I is the motor current with reactors

$$\mathbf{I}=\frac{E\underline{|0}}{\sqrt{3}}Z_t\underline{|\theta_1}=\frac{E\underline{|-\theta_1}}{\sqrt{3}Z_t} \qquad (7)$$

The drop in voltage across each reactor is given by

$$V_r=\mathbf{I}\mathbf{Z}_r=\frac{E}{\sqrt{3}}\cdot\frac{\underline{|-\theta_1}}{Zt}\cdot X_r\underline{|90\text{ degrees}}$$
$$=\frac{EX_r\underline{|90-\theta_1}}{\sqrt{3}Z_t} \qquad (8)$$

and the voltage across each phase winding of the motor is

$$V_m=\frac{E}{\sqrt{3}}-V_r \qquad (9)$$

The voltage at the motor with reactors expressed as a percentage of that without reactors is $\sqrt{3}\ V_m\times100/E$ while the per cent motor torque is $3V_m^2\times100/E^2$.

Applying these equations to the five reactors and the corresponding motors of Table IV and assuming the motors to have full-voltage locked-rotor currents of seven and ten times full load current, the effect

Table V. Application of Air-Core Reactors

Reactor	Inductance, Millihenries	Reactance, Ohms	Volts	Frequency	Maximum Horsepower
1	0.56	0.21	2,300	60	200
2	0.56	0.21	2,300	60	400
3	0.56	0.21	2,300	60	600
4	1.34	0.21	2,300	25	200
5	1.34	0.21	2,300	25	300
6	2.24	0.84	4,600	60	300
7	2.24	0.84	4,600	60	600
8	5.36	0.84	4,600	25	300

of the reactors on motor voltage and torque is shown in Table VI.

In making the calculations shown in Table VI the standstill power factor of the motors having an inrush of seven times full load current was assumed to be 0.35 and that for motors having an inrush of ten times full-load current 0.30. A full-load power factor of 0.85 was assumed for all motors. Table VI shows the small change in per cent power factor ($\cos \theta - \cos \theta_1$) $\times$ 100 caused by the air-core reactors at full load.

For a given series of reactors having a constant inductance, the voltage drop across the reactors is proportional to the horsepower of the motor. Obviously there will be a practical upper limit to the motor size with which the reactors can be used, and this will be decided by the reduction in motor torque that can be tolerated during starting. As in the case of the reactor size limitation, it appears that 600 horsepower on 60-cycle systems is a good practical limit of application, and that the starting torque requirements should be watched closely on large drives.

The effect of air-core reactors on motor torque during acceleration from rest is shown in Figure 6. The curves apply to a series of 2,300-volt 60-cycle motors having full voltage inrush currents of 6.65 times full-load current. These curves were determined from typical speed-torque and speed-current curves[5] for class *A* squirrel-cage induction motors, assuming a standstill power factor of 0.35 and a full-load power factor of 0.85.

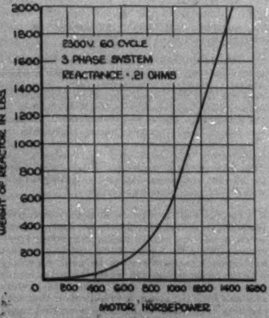

Figure 4. Weight of reactors versus motor horsepower

Air-core reactors used in this way, particularly on the larger sizes of motors, convert an "across-the-line" starter into an automatic reduced voltage starter without the use of an additional contactor and transfer relay.

Electromagnetic Forces

The method of mounting the air-core reactors in the controller enclosure is shown in Figure 7. The reasons for selecting such an arrangement of the coils are:

1. To reduce the mutual inductance between the coils and assure a reactance per line independent of phase sequence.
2. To provide individual and uniform mounting.
3. To provide simple and rigid assembly.

The eddy-currents induced in the wall of the steel cabinet are negligible at normal frequency. Any high-frequency oscillations during the interruption of the circuit will be damped more quickly by the eddy-current effect in the enclosure wall.[6]

With three coils mounted as shown in Figure 7, the electromagnetic forces between them produce torques about their perpendicular diameters, the greatest being that on the center coil marked (2). For coils of fixed dimensions and fixed spacing, the force between them is proportional to the square of the ampere-turns or proportional to LI^2 where L is the self-inductance of each coil. For the same fault kilovolt-amperes, the quantity LI^2 is constant for both 2,300- and 4,600-volt systems at the same frequency since the inductances are proportional to the square of the voltage and the fault current is inversely proportional to the voltage. The inductances also vary inversely with system frequency while the fault currents are independent of the frequency, hence the electromagnetic forces on reactors used on 25-cycle systems will be 2.4 times the corresponding forces on 60-cycle systems.

Three reactors were arranged for test as shown in Figure 7, reactors (1) and (3)

being rigidly fixed while the center reactor (2) was carefully pivoted about its vertical diameter. Current was led in and out of the center reactor by immersing the terminals in mercury-filled cups. An accurately calibrated spring was used in determining the torque required to return the reactor to its normal position when various values of 3-phase currents were passed through the three reactors. The measured torques were proportional to the square of the currents as expected, and by extrapolation the torque was estimated to be 75 pounds feet at 6,250 amperes, the current corresponding to 25,000 kva at 2,300 volts. If the current were reversed in reactor (3) the torque was negligibly small as expected.

The particular reactors used in the test were the 200-horsepower 2,300-volt 60-cycle reactors on Tables IV and V, consequently the torque for 25-cycle coils would be about 180 pounds feet. These torques are the mean values, the peak being twice as great or 150 and 360 pounds feet respectively. At the instant of fault the d-c components give initial total rms currents somewhat in excess of the steady-state currents. Allowing an additional factor of two for the effect of the d-c components, the torques become 300 and 720 pounds feet respectively. Unbalanced faults may increase these forces up to 50 per cent but even then the torques do not present any mounting difficulties.

Short-Time Current Ratings

Short-time current ratings of conductors are expressed in amperes for one-quarter second, one-half second or any other short time interval. The short-time current ratings of the reactors and any other components of the controller must be in excess of the maximum anticipated fault currents for the time the controller takes to interrupt the circuit. The smallest of the eight reactors, in Table IV, is wound with number 5 square wire and has a one-quarter second rating of 12,000 amperes. This is considerably in excess of that required since the interrupting time of the controller is of the order of 0.05 second.

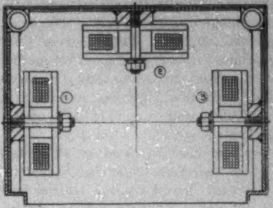

Figure 7. Arrangement of reactors in controller enclosure

Low-Voltage Applications (Up to 600 Volts)

A similar study was made of low-voltage systems with a view to determining the practical range of application of air-core reactors. The size and weight of the reactors themselves and their effect in reducing the voltage at the motor, particularly during starting, were the critical factors.

About 95 per cent of the activity in the low-voltage field is covered by motors up to 200 horsepower. In general, transformer banks are not larger than 3,000 kva, giving a maximum available kilovolt-ampere of about 50,000 at 6 per cent impedance. This results in fault currents of considerable magnitude on 'ow-voltage systems, for example 65,700 amperes at 440 volts. By a study similar to that made in the case of 2,300- and 4,600- volt systems, it can be shown that for maximum available fault currents in excess of 30,000 amperes, reactors may as well be designed for an assumed infinite available fault current. This is comparable to the conditions found with high-voltage reactors where available kilovolt-ampere is in excess of 200,000.

Following the same procedure as in the case of high-voltage systems, it was necessary to choose a limit for the fault current. If 10,000 steady-state amperes is chosen, and similar limitations in weight and starting torque are accepted, it appears that the range of application would be 100 horsepower at 220 volts and 200 horsepower at 440 and 550 volts. The 10,000-ampere limitation demands the use of controllers having rated interrupting capacities of 15,000 amperes or better including the d-c components.

Discussion

E. H. Alexander (General Electric Company, Schenectady, N. Y.): In this paper the author has treated, in a thorough manner, the design and use of air core reactors for the special requirements of mounting within the enclosure of a high-voltage high-interrupting-capacity controller. The recognition of the need for controllers of adequate interrupting capacity is indeed timely for it has long been a neglected equipment in the circuit between the source of power and the power utilization apparatus as far as interrupting capacity is concerned.

Recently, air-core reactors also have gained somewhat in popularity as a means for limiting short circuit current on low voltage a-c systems, especially in the case of relatively low ampere feeder circuits originating from a bus of high short-circuit capacity where the economics of a full capacity or cascaded circuit breaker is unattractive. This is recognized in the Leitch paper. In this case, as in the case of the high-voltage motor controller, the current limiting reactor as a means of reducing fault current has to be appraised on the basis of cost, physical size, energy losses, and the penalty of voltage drop which it produces under various conditions of load.

There are several points in Leitch's paper which I feel should have further amplification and clarification, as follows:

1. From the standpoint of a co-ordinated equipment, it is assumed that the hook-operated disconnecting switches, shown schematically in Figure 5 of the paper, have ample momentary current ratings to withstand the magnetic effects of the short-circuit currents permitted by the reactor. This, of course, pre-supposes the short circuit to be at or beyond the load side of the reactor. These currents could be as high as 10,800 amperes. It is for this same reason that a 50,000-kva controller was selected, even though the steady-state fault currents were limited to 25,000 kva.

2. The short-circuit values calculated for Table I give values at the transformer secondary which originate from the transformer only. The table does not take into consideration an allowance for induction or synchronous motor contribution on the low-voltage side of the transformer. In practical short-circuit studies, better evaluations or assumptions can often be made, without seriously complicating the short-circuit calculations, and these more careful results could lead very easily to different conclusions, in certain circumstances, with regard to equipment selection.

3. The effect of the reactors on motor torque plotted in Figure 6 of the paper does not appear to be a severe penalty to pay for the average motor application. While the author has stated frankly that application precautions must be used, especially with the larger motors and where the motor torque requirements tend to be close to the normal values available from the motor, it would appear that such checking may have to be done somewhat more carefully than he implies to be sure of avoiding trouble. Such applications as ball mills, tube mills, positive displacement pumps and crushers would certainly be examples requiring more elaborate

investigation to determine if the reduced torque caused by the reactors could be tolerated. On the other hand, leading power factor synchronous motors, when running in synchronism, would actually have their terminal voltage slightly increased by the presence of the reactor.

4. The thermal and mechanical phases of the reactor design were not covered in great detail. As far as the losses in the reactor are concerned, we would presume from the paper that they were 100 watts or less per reactor. I would like to ask the author what he considers good engineering practice for the temperature rise limitations of the copper used on the reactor winding for the various conditions of normal running current; prolonged high starting currents; and short-circuit conditions. The extrapolation of the torque values produced by the electromagnet forces between the reactors was treated in the paper. Whereas sound conclusions may be arrived at by such a method, it would seem that more reliable data could be obtained by full capacity overcurrent tests on completely co-ordinated motor controllers, not only to check the mutual forces between the reactors, but also to check the mechanical or bursting strength of each individual reactor.

5. With available power switching equipment limited to 150,000 kva interrupting capacity at 2,400 volts and 250,000 kva interrupting capacity at 4,160 volts, the need for embracing systems in excess of these values is rather small. That there are such systems, in excess of the above values in existence, is fully recognized but they are fortunately few and far between, and are by no means a compliment to sound distribution engineering.

F. H. Kierstead (General Electric Company, Pittsfield, Mass.): Leitch is to be complimented on his development of reactors for this service that are so small, light, and inexpensive.

The description shows the reactor to be a simple back-turn section coil without ventilating ducts. The dimensions of the conductor given in Table IV appear to be in error inasmuch as 3/32 by $1^{1}/_{4}$ inches fit the dimensions of the coil, the resistance and the weight that are given.

In achieving simplicity of construction, a sacrifice has had to be made to eddy losses in the winding and to ventilating area. This results in high watts per square inch of dissipating surface and, one would expect, high coil temperature rises over surrounding air. The losses in the metal nut welded to the enclosure under the coils are probably fairly high, and if so would furnish additional heat to the coils by conduction.

The losses in the reactor coils and the losses which these coils generate in the enclosure walls contribute to a general rise in air temperature within the enclosure.

Leitch has pointed out that this rise is 20 degrees centigrade above outside ambient.

One would expect the accumulated effect of these factors to result in rather high coil temperature rises above outside ambient. Perhaps Leitch will want to say what the actual ultimate rise was when carrying the full 100-ampere load current of the motor, and also, what class of insulation was used.

With the back-turn section used and the dimensions of the coils as given, the distance between the ends of the winding cannot be much greater than 3/8 inch. This distance has to stand 75 per cent of the line to neutral voltage of the circuit, $(0.75\times2{,}300/\sqrt{3})$ when undergoing short circuit. Furthermore, if these coils are built to American Standards Association specifications for current limiting reactors used on 2,300-volt circuits, they will have to stand 25 kv applied between winding and ground as well as 25 kv applied between terminals.

It is quite possible that the insulations standards set up for current limiting reactors are too stringent for industrial applications. The possibility of setting up an industrial standard could be explored profitably. However, the establishing of two insulation standards would have several disadvantages, and should be adopted only after careful consideration of all factors. Leitch may want to state what insulation level his coils will meet.

John D. Leitch: The hook-operated disconnecting switches shown in Figure 5 are provided with blade locks.

Table I was intended primarily to show how little additional reactance is required to take care of infinite available kilovolt-ampere compared with that required for 200,000 kva. The decision to design for infinite available kilovolt-amperes eliminates the necessity of considering the existence of any synchronous machines on the secondary side of the transformer.

Alexander is quite correct in stating that care must be taken in applying fault limiting air-core reactors to motors of larger horsepower to assure adequate starting torque. This limitation is covered in detail on Table VI. Frequently reduced voltage starting is a requirement on higher horsepower drives.

The paper is somewhat longer than the usual six pages, consequently space was not available to go into the thermal and mechanical details of the reactors. Only sufficient information was given to show how surprisingly small the reactors can be.

The 200-horsepower coil on Table IV has a temperature rise of 90 degrees centigrade at its rating. The 400-horsepower coil was never built, but from tests on other coils of approximately the same size, its temperature rise should not exceed 100 degrees centigrade at its rating. The thermal capacity of the reactors is quite large and will withstand repeated starts equally as well as the motor. Class "B" insulation is used throughout the coils and according to NEMA Industrial Control Standards[1] a temperature rise of 105 degrees centigrade is permitted although such standards do not specifically include air-core reactors.

The I^2R losses at 25 degrees centigrade should be kept as low as practical in order to reduce the total watts including eddy-current losses in the winding. A slight increase in the weights and greater consideration to the proportions of the coil not only reduce the I^2R losses but also the eddy current loss per pound. This results in less total watts and greater surface area and consequently lower temperature rise. It is quite possible to obtain a series of coils having less than 80 degrees centigrade rise with very little additional copper.

It is acknowledged that the determination of the electromagnetic forces is only approximate. Prior to the presentation of the paper, arrangements had been initiated for tests such as those suggested by Alexander.

Kierstead points out that in achieving simplicity in construction and mounting, a sacrifice has been made to eddy-current losses within the winding and to the ventilating area of the coil. This is the penalty that must be paid for such compactness and ruggedness.

The total flux is proportional to the current or horsepower for a given series of coils having approximately the same number of turns. The effect of this flux on the mounting stud and welded nut is negligible for the lower horsepowers, but is significant at 400 horsepower and up. It becomes necessary to use nonmagnetic stainless steel in mounting the larger coils and to increase the distance between the coil face and the wall of the enclosure. This demands consideration of enclosure size for the larger horsepowers. With increase in size of the coils, there is also an increase in the total watts, requiring a larger and perhaps louvered enclosure. Such ventilation is hardly necessary with the smaller coil particularly when the enclosure is large because of the presence of disconnect switches and bus bars above the reactors.

Kierstead discloses an error on Table IV. This is a typographical error, the 400-horsepower coil winding should be 3/32 by $1^{1}/_{4}$ inches not 3/32 by $1^{3}/_{4}$ inches, as stated.

It is fully appreciated that the coils must have high insulation levels. The double glass wire wound coils have been abandoned in favor of strap wound coils. The insulation between turns is 0.010-inch glass cloth impregnated with thermal-setting varnish. On test this insulation breaks down at 3,500 rms a-c volts. The strap wound coils indicated in the paper are of the 2-layer back-turn construction with 1/4-inch insulation between layers. This insulation extends beyond the outside diameter of the winding giving a creepage distance of $1^{1}/_{4}$ inches between outside turns which is more than adequate for 25,000 volts.

It is somewhat premature to discuss standards for current limiting reactors used with motor starters. It is possible to meet the present ASA standard C57-16, 1948[2] as far as continuous temperature rise and insulation levels are concerned.

Synopsis: A square-law power-level recorder is described which is a new and improved version of a type of recorder which measures a-c voltage (or power level) on a linear decibel scale by means of a motor-balanced slide-wire attenuator.[1] The detector, which is responsive to the mean square of the instantaneous voltage of its input, and the problems encountered in the insertion of this detector into the instrument, are described in detail. Other improvements in the circuit with the resulting improved performance are presented.

THE DEMAND for more accurate measurements of power levels, as well as the increasing interest in the frequency characteristic of voice and carrier channels, filters, high fidelity amplifiers, and so forth, has created the need for an instrument to record quickly and accurately these measurements.

In this recorder, the voltage to be measured is applied to the input terminals of a ladder-type slide-wire attenuator which is adjusted by the balancing motor so that the output voltage of this attenuator is always returned to a standard value. This method, which is the same as the standard manual method of making attenuation measurements, eliminates the need of designing an a-c amplifier having reproducible characteristics over a large range of input voltage, and also eliminates the need for a dynamic element with a logarithmic response.

In the operation of the recorder it is essential that a d-c voltage be produced which is related to the magnitude of the a-c input signal. This detector may be designed to function from its peak input voltage, from its average input voltage after rectification, or, preferably, from the mean of the square of its instantaneous input voltage. This "square-law" type of detector is preferred, because it handles an input composed of two or more components of different frequency in such a way that their relative phase has no effect upon the mean detector output.

The development of this type of recorder, which employs a square-law detector and incorporates other circuit improvements to obtain better performance, was started during the war to meet a specific need of the Naval Ordnance Laboratory.

The resulting instrument, Figure 1, has a scale linear in decibels, and a range of 40 decibels above a zero reference level of 0.0002 milliwatt with a 125-ohm input impedance. (Recorder ranges of 20 decibels, 50 decibels and 60 decibels also have been built.) The frequency error is less than 0.1 decibel between 20 and 200,000 cycles, Figure 2. Abrupt changes of power level of 30 decibels can be recorded in 1.5 seconds. The limit of error is ±1/3 per cent of full scale over its frequency range, provided peaks in the wave form of the voltage being measured do not exceed four times the rms value of that voltage. The performance of the recorder is independent of line voltage variations or changes in frequency of the line voltage. It requires no batteries, being entirely a-c operated. The record is made with ink on a chart 10 inches wide, driven by a synchronous motor at standard speeds of 2 inches per minute or 4 inches per hour.

Figure 3 shows a sample chart made by a 40-decibel recorder. It was obtained by connecting the recorder to a decade attenuator which was supplied from a constant 1,000-cycle source. The attenuator was changed in 3-, 10- and 30-decibel steps, causing the recorder to plot the chart shown. It is apparent from this record that even though the recorder is fast, its error is less than 1/3 per cent of full scale, the dead range is negligible, and the recorder draws a smooth curve without overshooting the balance point.

General Description

In the operation of the recorder, the a-c voltage to be measured is connected to a ladder-type slide-wire attenuator, Figures 4 and 5. The attenuator output is amplified by an a-c amplifier; it then goes through an inverter stage before being "detected." A full-wave detector employing two pentodes is used. The circuit constants of the tubes are adjusted so that the detector has a square-law response. In order to obtain the same type of recorder performance for increasing signals as for decreasing signals, the output of the detector is filtered and limited. This d-c voltage is reduced by a standard d-c voltage and by the d-c voltage generated by a tachometer, the remainder being amplified by a d-c amplifier. The tachometer, mounted on the slide-wire motor shaft, generates a voltage proportional to the speed of the recorder and thus prevents overshooting. The output voltage of the d-c amplifier goes to the grids of the double-triode converter. This tube controls the firing of the two thyratrons that control the direction of rotation of the slide-wire motor. When the voltage across the grids of the double-triode has one polarity, one thyratron will fire, and the motor will move the slide-wire attenuator towards the balance position. A reversal of polarity causes the second thyratron to fire and the motor to move the attenuator in a reverse direction, but again towards the balance position. In all cases the motor moves

The authors are very grateful to R. E. Watson for his assistance in this development.

Also presented at the National Electronics Conference, Chicago, Ill., November 4–6, 1948.

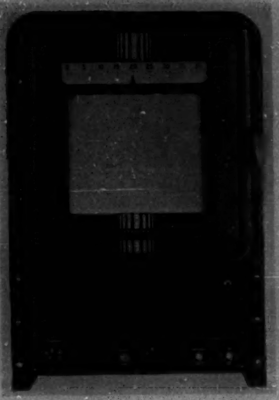

Figure 1. Square-law power-level recorder

the attenuator so that the input to the a-c amplifier is always brought to the same a-c voltage when the recorder is at the balance position.

The position of the slide-wire attenuator, which is indicated by the pointer of the recorder and recorded by the pen on the chart, is a measure of the power level of the input to the recorder above the zero reference level.

Component Parts

Slide-Wire Attenuator

The slide-wire attenuator, Figure 6, is a continuously-variable unbalanced-π-section attentuator, in which the series coils are the equal sections of a tapped slide-wire; the shunt coils are connected to these taps. Since the attenuator is contiuuously variable, the recorder will plot a smooth record. The decibel range of the recorder is determined by this attenuator.

The frequency characteristic of the recorder depends on the frequency characteristic of the attenuator, as well as that of the a-c amplifier, inverter, and detector. As can be seen from the inserts of Figure 6, the slide-wire is wound reversed-turn with constantan wire on a hard-rubber rod, and the shunt coils are woven resistors of manganin that have negligible reactance at the frequencies used.

Since the attenuator is at the input end of the recorder, Figures 4 and 5, the input impedance of the recorder is the characteristic impedance of the slide-wire attenuator.

In an attenuator of this type, the attenuation in decibels at successive shunt coils varies linearily with slide-wire position, but between shunt coils the variation is not linear. However, by using sufficient shunt coils, this error can be made negligible. If the decibel range of the recorder and the allowable error are known, the number of sections that should be used can be determined easily. (Equations and graphs used in determining this are given in the Appendix of W. R. Clark's paper.[1])

A-C Amplifier

The output of the attenuator is amplified by the a-c amplifier, Figures 4 and 5, which has a flat frequency response, caused by low-value plate resistors, large coupling condensers, and low-frequency compensation networks.

The gain of this amplifier determines the input level at which the recorder will operate. The lowest input of all standard recorders is 0.2 microwatt or 5 millivolts.

A gain control, marked "Input Level," Figure 5, is provided so that the input level can be adjusted over a range of almost ten decibels without otherwise affecting the operation of the recorder.

Inverter

A conventional single-tube-type inverter is used which employs equal resistors in the plate and cathode circuits

Detector

The desired property for the plate-rectification-type of vacuum-tube square-law detector is that the change in its plate current be proportional to the square of the instantaneous signal voltage. This change of plate current must develop a voltage across a load resistor at the input to a resistance-capacitance (*RC*) filter. Because of the averaging action of this filter, its output (measured from the quiescent state) will be proportional to the square of the instantaneous voltage applied to the detector input.

The search for the tube with the desired properties for a square-law detector started with the realization that a perfect linear variation of transconductance with control-grid voltage means a perfect quadratic variation of plate current with grid voltage see Figure 7. Certain pentodes, in particular the *12SH7*, approach this characteristic, under selected values of the operating parameters.

Since the quiescent grid voltage is at or very near to cutoff, negative swings of the grid are off the quadratic curve; hence, another tube must be used, with its grid driven from the other half of the phase inverter. The two tubes share a common plate load resistor which serves to combine their outputs. The two-tube detector practically eliminates the fundamental frequency from the detector output, and so eases the low-frequency requirements of the *RC* filter which follows the detector.

There is overlapping of the two tubes during those parts of the cycle for which the signal amplitude is less in value than the margin between bias and cut-off. Owing to the addition of the plate currents while the signal is in this region, it is not required that the cut-off of the tubes be as sharp as Figure 7 suggests.

It was found necessary to age new detector tubes 48 hours, with normal heater and plate currents, before their characteristics became stable. It was

necessary to match tubes for the detector, and all tubes could not be used. Out of the 24 tubes tested, eight sets (16 tubes) were obtained.

In order that the d-c output would vary only with a-c input and would be independent of line voltage variations, it was necessary to use a well-regulated d-c supply voltage. Since this same regulated voltage supply is used to operate the d-c amplifier, and since direct coupling is used between the detector and the d-c amplifier, it was desirable to limit the plate voltage of the detector circuit to 45 volts, in order to have sufficient voltage available for the d-c amplifier to obtain the required power output.

It was not convenient to test the relation between instantaneous detector output and its instantaneous input, hence steady sine-wave signals were applied to the input, and the filtered d-c output was measured with the limiter and d-c amplifier disconnected. (A method of testing the square-law response of the complete recorder is described in the Appendix.) The results are plotted in Figure 8. It can be seen that the characteristic of each tube individually deviates from a square-law, but that the two tubes together do

produce a square-law relation. The resistors in the screens of each tube extend the range of the square-law relation upward, as can be seen from the same figure.

The setting of the bias of the tubes controls the slope of the logarithmic curve relating the a-c input signal to the d-c output voltage. For the given operating conditions, a grid bias of -1.85 volts gave a very good square-law response. Larger values of negative grid voltage give a higher power law, while smaller values give a lower power law.

It is important that the square-law relation hold for a considerable range of voltages above and below the operating point, in order to adequately take care of peaked wave shapes. In the final design the square-law relation held over a decade of a-c input voltages, and the operating point was set at the mid-point ($\sqrt{10}$) of this range. Voltage peaks may therefore reach a value of $3\sqrt{2}$, or approximately four times their rms value, without causing overload and departure from square-law performance.

The characteristics of the tubes used, in addition to determining the law of the response, also affected slightly the operating level and, to a lesser degree, the frequency characteristic. However, the characteristics of the tubes, after aging, remained stable and did not vary appreciably with time.

The resistor and capacitor between the detector tube and the next tube, the limiter, are used as a filter to smooth out the output of the detector and thus obtain a steady a-c voltage. The time constant of this resistance-capacitance network must be low enough not to affect the speed of the recorder, yet not so low as to provide insufficient filtering at the low frequencies. Insufficient filtering causes the recorder to move back and forth continuously at the balance point, in an attempt to follow the instantaneous value of the voltage applied to the grid of the d-c amplifier.

In order to obtain proper operation of the recorder, and insure that upscale unbalances require the same time for rebalancing as downscale unbalances of the same magnitude and have the same type of response without overshooting, it was necessary to limit the effective output of the detector, to obtain the symmetrical curve of limited detector d-c output (linear scale) versus logarithm of a-c amplifier input voltage shown in Fig. 9. A triode, connected as a diode with proper d-c bias, was used to perform this limiting function. In order that it should not enter into the detector action, it is placed after the *RC* filter following the detector.

Since the slide-wire position is linear in decibels and logarithmic with voltage, this curve can also be considered as a limited detector-output versus slide-wire-position curve. When the recorder is balanced, the limited detector output is at the balanced position, Figure 9, which is the center of the *S*-shaped curve. Since the parts of this curve on either side of the balance position are symmetrical, a given displacement of the recorder from the balance position, in either direction, will produce the same change in the limited detector output, and will cause the recorder to rebalance with the same speed in either direction. This type of response

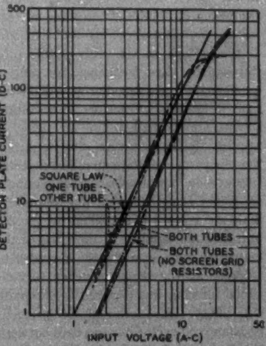

Figure 8. Square-law response of detector

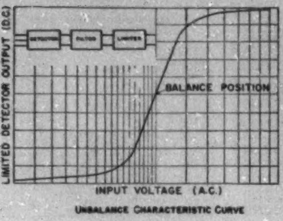

Figure 9. Unbalance characteristic curve

curve permits maximum recorder speed without overshooting.

In order to take care of variations in tubes, a control which is called the "Symmetry of Response" control, Figure 5, is provided, so that the limited detector output can be adjusted to be at the center of symmetry when the recorder is balanced. This enables the speed of the recorder to be adjusted so as to be the same in either direction whenever the characteristics of the tubes change.

The d-c voltage from the detector is opposed by a standard d-c voltage obtained from the regulated power supply, and by the tachometer voltage. The resulting voltage is applied to the d-c amplifier. This standard d-c voltage is equal to the output of the detector-limiter combination for a pre-selected input to the a-c amplifier, and is used to bring the input to the d-c amplifier to zero and thus permit the recorder to balance. The use of the tachometer voltage for damping is well known.[2]

The square-law detector presents a difficulty in the filtering problem. The action of the converter, as described later in the paper, depends upon having line-frequency (60 cycles) alternating voltage for the plate supply of its double triode. If the voltage on the grids of this tube differs from line frequency by only a small amount, the recorder will follow the beat frequency. Therefore, if a voltage having about one-half line frequency is applied to the recorder, the frequency doubling action of the square-law detector produces in its output a voltage having a frequency near that of the line frequency. This a-c voltage is amplified by the d-c amplifier and applied to the grids of the converter tube, causing the recorder to respond at the beat frequency. Additional filtering was required to eliminate this effect. A 3-terminal *RC* bridged-resistance 60-cycle filter was used between the limiter and the d-c amplifier. Tests of the recorder's action, with large changes of line frequency, showed that this filter rejects over a band of frequencies broad enough to completely solve this problem. This type of filter provides sufficient filtering with minimum time constant, and permits greater recorder speed than would be possible with filters of other types.

D-C Amplifier

A change in the a-c input voltage to the attenuator of 0.1 per cent does not produce a sufficient change in the limited detector output to operate the converter stage. A single-stage triode d-c amplifier, Figures 4 and 5, provides sufficient amplification to obtain enough sensitivity for even a 10-decibel range. Higher decibel ranges require a reduction in the d-c amplification. This is accomplished by shunting the plate of the d-c amplifier tube with a resistor, thereby lowering the load impedance of this stage and decreasing the gain. In order not to affect the operating point of the tube, this resistor is connected from the plate of the tube to a point on the voltage divider equal in d-c potential to that of the plate when the recorder is balanced. A capacitor across the load resistor in the plate circuit smooths out any pulses which may be present.

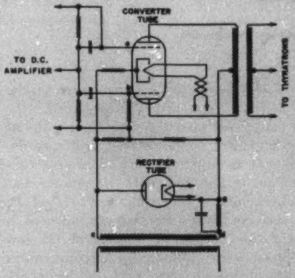

Figure 10. The converter (thyratron firing circuit)

Converter

The purpose of the converter, Figure 10, is to take the output of the d-c amplifier, Figures 4 and 5, and use it to operate the correct thyratron, so that the recorder slide-wire will be driven to the balance position. A further complication occurs since the thyratrons are at ground potential, while the d-c voltage obtained from the d-c amplifier is 105 volts above ground. Insulating transformers are used, and the converter changes the d-c output of the d-c amplifier to an a-c voltage, of the correct phase to operate the proper thyratron.

Each plate of the double triode, Figure 10, is connected to one end of a center-tapped primary winding of a transformer. The secondary winding of the transformer supplies voltages of the proper phase to the grids of two thyratrons. The plate supply for the double triode is obtained from a half-wave rectifier; its wave shape is shown in Figure 11. If this rectifier were perfect, there would be no negative component. This wave shape occurs because when *d* is minus with respect to *c* current flows through the rectifier, and the voltage drop across it is very low, but not quite zero, thereby making *e* minus with respect to *c*. When *d* is plus with respect to *c*, the rectifier does not pass current, and the voltage across it is high. When one of the grids of the double triode becomes positive with respect to the other, the plate current of that triode will become greater than the plate current of the other triode. At time *t*, Figure 11, the supply voltage goes sharply to zero and reverses polarity. This supplies negative plate voltage, but, what is more important, it also supplies negative grid-bias voltages to the triodes. This rapid shift of the grids to the negative region cuts off the plate currents of the triodes very sharply, and the rapid collapse of the flux in the output transformer produces a peaked wave in its secondary. Without this cutoff, the current would continue as a result of the inductance of the output transformer. The triode having the more positive grid passes more plate current than the other triode; thereby it determines the direction of this peak.

The secondary voltage from the transformer is used to turn on one or the other of the thyratrons. The polarity of the voltage across the grids *a* and *b* determines the phase of this peaked voltage, and so determines which thyratron is turned on, and also determines in which direction the motor is turned. The mag-

Figure 13. Test for square-law response

nitude of this voltage across *a* and *b* determines the height and breadth of the pulse to the thyratrons. Since the higher peaks are broader at the base, they fire the thyratrons somewhat earlier in the cycle, thus giving a stronger pulse to the motor for large unbalances, which is desirable. When the recorder is balanced, the voltage across the grids *a* and *b* is zero, and there is no output voltage across the secondary of the output transformer.

The use of a peaked voltage to fire the thyratrons is a desirable feature of the circuit, since the phasing between this voltage, which is supplied to the grid of the thyratron, and the 60-cycle sine-wave plate voltage, does not have to be adjusted as accurately as is generally necessary when sine-wave voltages are used on the grid as well as on the plate of the thyratron.

The heater, plate, and bias voltages for the converter must be obtained from separate windings on the power-pack transformer, since they are also at 105 volts above ground. These voltages do not have to be regulated, since any change in their values, caused by normal line voltage variations, will not affect the operation of the converter. The plate and bias voltage, Figure 5, must be obtained from the same supply as the plate voltage of the thyratrons to ensure the correct phase relation between the two.

THYRATRON ASSEMBLY AND RECORDING UNIT

The output of the converter, as stated before, is applied to the grids of the thyratrons, Figures 4 and 5, which drive the three-lead, split-field, series reversing motor that is mechanically coupled to the slide-wire attenuator, the tachometer, and the pen. This part of the instrument is the same as the corresponding part in a standard type *A* Speedomax recorder.

POWER SUPPLY

The power supply for the recorder, exclusive of the plate and heater voltages for the converter and thyratrons, must be very well regulated, Figures 4 and 5. This is particularly true of the power supply for the detector, the d-c amplifier, and the standard-voltage supply, since any variation in their power supply enters directly into the operation of the recorder, and will affect its performance. Somewhat greater variations in the power supply of the a-c amplifier would be permissible, since these variations do not greatly affect its gain, which is all that need be held constant. Variations in the power supply of the converter will affect only the sensitivity of the recorder.

For stable recorder operation, especially on the low-decibel ranges, the d-c power supply must be held constant to 0.1 per cent. This requires an electronically-regulated power supply, Figure 5. Regulation obtained by this method was considerably better than that required. The heaters, as well as the plate, screen, and bias voltages, of all the tubes in the a-c amplifier, inverter, and rectifier, and the d-c amplifier, were supplied from this source.

Operation Controls

All controls are centralized on the front panel shown in Figure 1. There is a "Line" switch, Figure 5, to control the a-c power supply; two switches to control the paper drive; a "Bias" switch; a "Bias" control, used to adjust the bias of the thyratrons; and an "Input Level" control. This last control is provided so that the recorder can be adjusted to read decibels above or below a definite power level. To make this calibration, the external source should be adjusted to the desired power level and the "Input Level" dial adjusted so that the recorder balances at zero on its scale. These adjustments do not have to be made every time the recorder is used, but they should be checked occasionally.

Appendix. Over-all Test for Approach to Square Law

In the body of the paper, there is described the method used to determine the detector characteristic. By plotting the logarithm of detector output versus the logarithm of its input, the closeness of approach to the square law could be determined. These plots were essential in guiding the development work, but a simpler test was sought which would not require so much measuring and plotting, and which would not require breaking into the recorder circuit, but would test the recorder as a whole for that characteristic for which the square-law response was most desired.

Figure 12 shows how a sine wave, of amplitude three, and its third harmonic, of amplitude one, combine to form an irregular wave having a peak, rms and rectified average value. When the phase of the third harmonic is reversed, as shown at the bottom of the figure, the composite wave takes a very different shape. The peak value is obviously greater. The rectified average can be seen to be less (only one added area and two subtracted areas). The rms value is unchanged, being unaffected by the relative phase between the two components of different frequency, as is suggested by the brief equations in the figure. The cross-product term produces new frequencies in the output, but it produces no contribution to the d-c component.

Consideration of these facts lead to the simple test of Figure 13. The recorder is first connected through an isolating resistance pad to an oscillator delivering a voltage of frequency f_1, as shown at the bottom. The pen is steady and plots a straight line. f_1 is then removed, and there is connected a second source of frequency $3f_1+\Delta$ where Δ is only a fraction of a cycle per second. Again, the pen is steady and plots a straight line. When f_1 is reconnected, the recorder moves upscale because of the combined inputs. If the pen plots a wave of frequency Δ, the detector response deviates from that of a square law. When the pen is steady and plots a straight line, the detector response can be considered satisfactory for recorder operation.

Distribution Transformer and Secondary Conductor Economics

BRYCE BRADY
MEMBER AIEE

Synopsis: The possibilities are investigated of lowering the cost of electric distribution in residential areas by using distribution transformers larger than required for thermal reasons to control voltage flicker; banking secondary mains to control voltage flicker; and using aluminum conductors instead of copper. The conclusion is reached that all three of these have a place in designing today's electric distribution systems.

MOST electric utilities operate more mileage of 120/240-volt single-phase secondary distribution mains than any other transmission or distribution voltage. It is important that such secondary lines and the size and spacing of the associated distribution transformers be designed for over-all economy.

The advent of more and more appliances which cause voltage flicker in residential areas makes control of flicker a prime design consideration. Most of the flicker voltage drop resulting from the starting of small motors occurs in the distribution transformers and the secondary conductors.

The most accurate approach is to design the transformer-secondary system for total allowable flicker and steady voltage drops, and to let over-all economics determine how much voltage drop should occur in the transformer and how much in the secondary main. The result of using this approach on a system with reasonably high service quality is that thermal capability ceases to be the governing factor in selecting transformer sizes in many residential areas.

Objectives

One of the objectives of this study is to determine the most economical loading of distribution transformers under various conditions. Another objective is to define the conditions under which secondary banking, as a means of controlling flicker, is economically justified. A third objective is to make an economic comparison of copper versus aluminum as secondary conductors under current price conditions.

Improving Existing Systems

The annual load growth on existing systems results usually in overloaded transformers, too much voltage drop, or excessive voltage flicker in the combined transformer-secondary system. In most cases such growth can be cared for by replacement and rearrangement of distribution transformers. On the system with which the author is associated, single-phase transformers up to and including 25 kva are installed at the top of the pole and can be moved from one pole to another without pole replacement and with little expense. Transformer locations are not considered permanent, but merely to be used until changing load conditions dictate that some other location would be more advantageous. The pertinent questions in periodic rearrangements to handle load growth are: What size transformers should be used, and how far apart should they be spaced?

Figure 1 shows the general form of the solution to this problem. This case is typical of nearly all of the practical situations encountered in distribution practice in that the most economical transformer size and spacing cannot be used because the quality of service would be unsatisfactory. The best that can be done is to choose the most economical transformer size and spacing which will meet the desired service standard.

In this example 10-kva transformers spaced 813 feet are more economical than either larger or smaller transformers where number 0 aluminum secondary conductors are used on the radial plan and the load density is 10 kva per 1000 feet.

The quality of service to be delivered by a distribution system has a great deal to do with its cost. In this and all other examples cited in this paper, steady voltage drop in the transformer plus the secondary main is limited to 6.6 volts. This is considered satisfactory on urban circuits equipped with voltage regulators. Flicker voltage drop in the transformer plus the secondary main resulting from the starting of 1/4-horsepower 115-volt motors is limited to four volts. This flicker is considered satisfactory provided it does not occur more often than six or seven times per hour. The same design limits the flicker resulting from the starting of 1/2-horsepower 115-volt motors to eight volts, which is considered satisfactory if it does not occur more often than once per hour. Larger motors are required to use the 230-volt connection. Transformer loading is limited to a maximum of 140 per cent of nameplate rating. No minimum transformer loading is recognized as a design limitation.

The total annual cost in Figure 1 includes taxes, interest, and depreciation on the investment in transformers, secondary conductors and variable appurtenances; cost of losses in transformers and secondary conductors; and maintenance of transformers and fuses. Iron losses are evaluated at $42 per kilowatt-year and copper losses at $14 per peak kilowatt-year. Other premises are listed in the Appendix and are used consistently throughout the paper.

The data from Figure 1 are plotted as

Paper 49-10, recommended by the AIEE transmission and distribution committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949, and at the South West District meeting, Dallas, Tex., April 19–21, 1949. Manuscript submitted November 15, 1948; made available for printing January 5, 1949.

BRYCE BRADY is chief distribution engineer with the Oklahoma Gas and Electric Company, Oklahoma City, Okla.

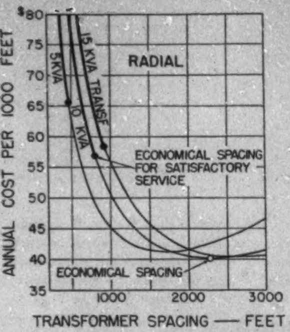

Figure 1. 10-kva transformers spaced 813 feet provide the most economical satisfactory service in a residential area where the load density is 10 kva per 1,000 feet and the 120/-240 volt secondary conductors are number 0 aluminum on the radial plan

functions of transformer loading in Figure 2. It is pertinent to note that 10-kva transformers loaded 82 per cent are more economical than smaller transformers loaded more heavily. This simply means that the capability to deliver the desired quality of service can be purchased more cheaply in a larger distribution transformer than in any other way.

In these examples the design limitation is the flicker resulting from the starting of small motors. If the secondary mains are banked so that starting current is supplied from two directions, and so that two or more transformers can contribute to the starting of the motor, then 15-kva transformers spaced 1,667 feet become most economical as shown in Figure 3. The result of banking is that the cost of distribution drops from $57 per 1,000 feet on the radial plan to $45 on the banked plan and the most economical transformer loading rises to 111 per cent as shown in Figure 4.

The most economical transformer size, spacing, and loading which will meet the required quality of service were ascertained in accordance with these methods for several types of conductor and a wide range of load densities. The results of this investigation are shown in Table I.

Where to Bank Secondary Mains

Distribution engineers do not all agree as to the merits of banking secondary mains. Most would undoubtedly agree that the principal advantage is reduction of voltage flicker. This is the only advantage evaluated in this paper. The conclusions which follow are, therefore, on the conservative side.

The total annual cost of each economical transformer-secondary combination listed in Table I is plotted in Figure 5, which shows that banking of secondary mains has too much merit to ignore at the lighter, and very commonly encountered, load densities. Nor can the advantages be dismissed as too much trouble, for the "trouble" has already been evaluated in the curves as the cost of two yearly inspections of secondary fuses plus 17 per cent replacement per year. Banking by means of circuit breakers instead of fuses would undoubtedly show similar results.

The curves show that secondary mains should be banked in all areas of less than 40 kva per 1,000 foot load density where number 6 copper is used; in all areas of less than 25 kva density where number 4 copper or number 2 aluminum conductor is used; and in all areas of less than 18 kva load density where number 2 copper or number 0 aluminum is used for secondary conductors. The curves are based on the premise that there are sufficient small 115-volt motors, existing or prospective, to justify holding the voltage flicker on all parts of the system to standards as discussed previously. Sufficient saturation of larger motors and electric ranges and the evaluation of the benefits of banking in equalizing steady voltage drop and transformer loads would extend the desirability of banking to higher load densities than shown.

Choice of Conductor for New Systems

Considerable labor is required to replace secondary conductors once they are installed and the service drops connected. It is usually most economical to make an initial installation of some size which will be suitable for continued use for many years as the load grows. Comparison of the annual cost curves in Figure 5 shows that number 4 copper is more economical than either larger or smaller copper conductor under the premises of this study. If a higher quality of service is to be rendered, then number 2 copper may be more economical. Similarly, it is apparent that number 0 aluminum is more economical than either smaller or larger aluminum conductor. This was found to be the most economical size whether the conductor is steel reinforced or not.

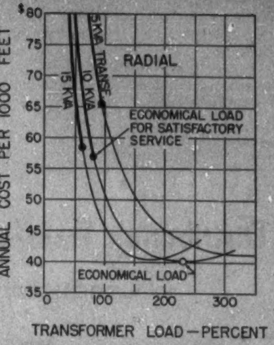

Figure 2. 10-kva transformers loaded 81 per cent are more economical than smaller transformers loaded more heavily under the conditions stated in Figure 1

Unfortunately it is impossible to attain 100 per cent banking of single-phase secondary mains because of irregular platting, necessity of balancing primary circuits, and similar reasons. Perhaps the best that can be done under average conditions is 50 per cent banked and 50 per cent radial. Making this assumption, the annual cost curves for number 4 copper, bare and weatherproof, and for number 0 aluminum, with and without steel reinforcing, are compared in Figure 6. Quite appreciable savings are available by using aluminum instead of copper.

Over a decade of experience with bare secondary conductors, in urban as well as rural areas, has led to the conclusion that weatherproof covering is an unnecessary luxury. All covering materials cost more per pound than copper. Bare conductors are inherently stronger by virtue of less weight, less resistance to wind, and less

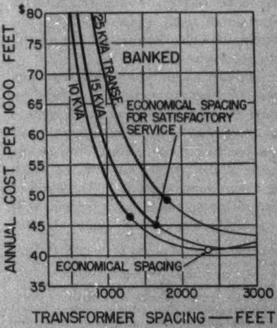

Figure 3. Banking of secondary mains reduces the total annual cost of the radial system in Figure 1 from $56.90 to $45.10

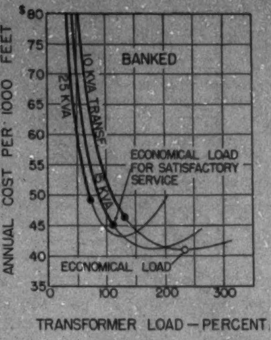

Figure 4. 15-kva transformers loaded 111 per cent are most economical if the secondary mains are banked

accumulation of glaze. Although arcing may be more frequent, it is less apt to cause burndown, because generally the arc does not remain concentrated at a single point. Altogether, it is the opinion of the company with which the author is associated, that part of the money which would be spent for weatherproof covering can be spent more wisely for increased clearance between the bare conductors; also that under current price conditions the savings that are possible by using aluminum instead of copper are worth going after.

Most Economical Transformer Loading

There can be no profit in loading distribution transformers to thermal capability, that is, to the peak load beyond which the life of the transformer is materially shortened, if it becomes necessary to make up for excessive flicker or steady voltage drop in more expensive ways. Likewise, it is a waste of time to calculate the most economical load on the transformer alone, without considering the secondary conductors, in situations where flicker or steady voltage drop in the transformer plus secondary circuit constitutes the design limitation.

The most economical transformer loadings which would render satisfactory service with a particular secondary conductor at a particular load density was ascertained in Figures 2 and 4 upon the premise that it is immaterial whether flicker and steady voltage drops occur in the transformer or in the secondary conductors. This premise is strictly correct in the case of flicker and is approximately

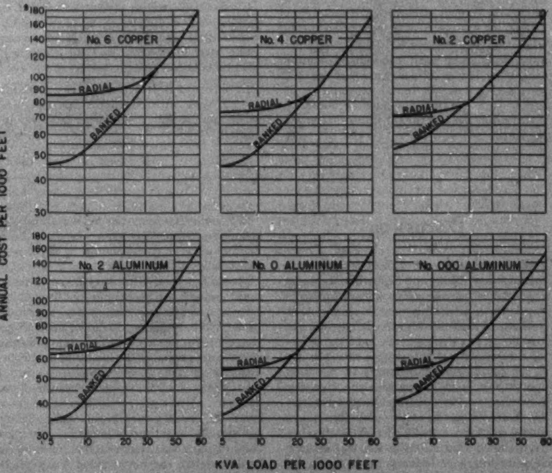

Figure 5. Economy of banking secondary mains is more pronounced at the lighter load densities

correct in the case of steady voltage drop, to the extent that voltage regulators on primary circuits are unable to compensate for noncoincident voltage drops of various magnitudes to different customers on transformer-secondary systems.

Each of the most economical transformer loadings for the various situations listed in Table I was determined upon this premise. The most economical transformer loading ranges from 22 per cent to 53 per cent depending upon the size of the conductor, on radial systems where the load density is 5 kva per 1,000 feet. At 10-kva density the most economical loading ranges from 43 per cent to 105 per cent. On banked systems and at higher load densities on radial systems, the most economical loading ranges from 85 per cent to 140 per cent. These percentages pertain to particular cost data and quality of service but are sufficiently general to justify careful appraisal of the over-all economy of loading distribution transformers to thermal capability in lightly loaded areas.

Conclusions

The premises and methods pursued in this study lead to the following conclusions:

1. The loading of distribution transformers to thermal capability of say 140 per cent is not economical if it is necessary to make up for the voltage drop in ways more expensive than installing larger transformers. On radial secondary systems it is not economical in general to load distribution transformers as high as 100 per cent of nameplate rating where the load density is 10 kva or less per 1,000 feet. The most economical loading may be as low as 22 per cent. On banked secondaries and on radial secondaries at higher load density, the most economical transformer loading ranges upward from 85 per cent.

2. The banking of secondary mains is definitely an economical method of limiting the flicker resulting from the starting of small motors in areas with load densities up to 18 to 40 kva per 1,000 feet, depending upon conductor size and material. Banking at higher load densities may be justified by other considerations.

3. Aluminum, with or without steel reinforcing, is attractive as a secondary conductor under current price conditions.

Appendix. Premises

1. Flicker voltage drop to be a maximum of four volts in transformer plus secondary produced by the starting of a 115-volt motor requiring 20 amperes at 60 per cent power factor.

2. Steady voltage drop to be a maximum of 6.6 volts in transformer plus secondary.

3. Transformers to be loaded a maximum of 140 per cent. No minimum.

4. Steady voltage drop in 120/240 volt 3-wire secondary based on unbalanced currents in the proportion of 83 per cent to 100 per cent.

5. 100 per cent load balance in transformer.

6. 90 per cent power factor.

7. Load distributed uniformly along secondary mains which are presumed to be straight without loops.

8. Transformers spaced uniformly along secondary main.

9. Diversity between loads on adjacent transformers is ignored.

10. Secondary conductor spacing to be 12 inches.

11. Annual cost on investment based on conductor prices of $0.31, $0.24, and $0.27 respectively for bare copper, aluminum cable steel reinforced, and all aluminum, plus installation costs.

12. Investment in secondary deadends (which vary with conductor material) and secondary banking fuses (where used) is included.

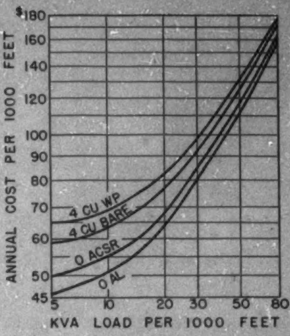

Figure 6. Worthwhile economy is available by using aluminum instead of copper for secondary conductors

13. Investment in poles and anchors is considered equal for all conductors studied, and is not included.

14. Transformer investment includes one fuse cutout, one lightning arrester, one ground and all installation costs.

15. Annual maintenance of transformers is included.

16. Annual maintenance cost of secondary banking fuses is included (two inspections plus 17 per cent replacement per year).

17. Copper loss in transformers and secondary conductors is based on 1,140 equivalent hours per year.

18. Iron loss is corrected to 122 volts.

19. Annual cost of 1-kw copper loss, $14 (includes energy cost plus demand cost in proportion to contribution to annual system peak load).

20. Annual cost of 1-kw iron loss, $42 (energy plus demand cost).

21. Transformers are mounted on the pole at primary voltage level and can be relocated at small expense (without pole replacement).

Discussion

H. E. Campbell (General Electric Company, Schenectady, N. Y.): The author shows us again the advantages of secondary banking. Figure 5 of his paper shows clearly that banking pays dividends especially when the load density is light and secondary conductors are small and the system must be designed for flicker conditions. It has been pointed out in his paper that the diversity between customers on different transformers has been omitted. However, this point should not be overlooked entirely. Studies have shown that distribution transformer capacity might be reduced by 10 to 15 per cent when transformers are banked as compared with radial systems at high load densities.

The point made by the author about the economies realized by using aluminum conductors on secondaries should be of interest to all utility men.

Brady has shown that for his system costs in some cases, it pays to operate distribution transformers underloaded. It is not clear to me from the paper just how the distribution transformers are changed around on the system to operate at the lowest annual cost. Table I of the paper shows the size of transformer and its loading for various load densities. Obviously, a system must grow from one density to a higher one. Many utilities have set up procedures whereby they change out a transformer when it is loaded up to a maximum value, and replace it with a larger one that will be loaded to only a fraction of its rating. I presume that this is the way Figure 5 was obtained.

I believe that the problem of economics of distribution transformers and secondary conductors is a little more complex than shown by this paper. The anticipated load growth and actual cost of changing transformers will influence the economics of changing transformers. Figure 1 of the discussion will show this point. Here a load growth of 10 per cent per year has been chosen, and the density has been plotted for an original value of 5 kva per 1000 feet for the next 15 years. Brady's paper indicates that when there is a number 0 aluminum secondary, a 10-kva transformer should be used for the first 13 years, and then a 15-kva transformer should be used. However, the difference in cost curve shown in Figure 1 of the discussion shows that over a 13-year period, it would cost only $18 extra to use 15-kva transformers instead of 10-kva trans-

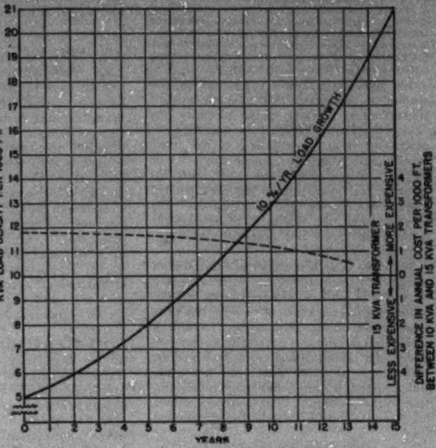

Figure 1. Dollars difference in annual cost between using a 10-kva versus a 15-kva transformer for a 10 per cent per year load growth

formers. Thus, if it cost more than $18 in labor to change a 10-kva transformer, then 15-kva transformers should have been installed originally. This cost of changing the size of transformers varies quite widely between utilities and between various sections of the country. Figures as low as $20 per installation for small transformers and as high as $80 per installation for large transformers have been quoted. This indicates that for this assumed load growth it would have been better to have installed the larger transformer initially.

The slower the load growth, the more one can afford to spend for changing transformers and vice versa. Load growth and cost of changing transformers, I believe, should be included in economic studies such as this.

L. T. Guess (Aluminum Company of America, Pittsburgh, Pa.): There are a number of technical papers on economic principles as applied to transmission lines. However, the technical literature as applied to distribution lines is rather limited. Perhaps this is because the factors peculiar to distribution systems do not lend themselves as well to analytical analysis. Even though it is not expedient usually to adopt the most economical size of conductor as calculated by Kelvin's classical theory, this "law" is generally recognized as a basis for economic studies. Application of this theory gives the most economical size for copper in circular mills to be equal to 590 $\sqrt{C/AP}$ and for aluminum to be 1,360 $\sqrt{C/AP}$ where C is equal to the cost per kilowatt-year of wasted energy, A is the per cent interest and depreciation, and P is the cost per pound of conductor installed. It is evident that if the most economic choice could be made on conductor and power-loss cost, it would be to use a larger size aluminum conductor than the equivalent copper conductor based on resistance. Naturally, the conditions peculiar to the distribution system under study will modify the choice. Brady's paper points out a logical approach to a distribution study and can be used as a guide by engineers who may wish to use slightly different assumptions.

Howard P. Seelye (The Detroit Edison Company, Detroit, Mich.): A comprehensive study of the various phases of the economics of secondary design, made in The Detroit Edison Company several years ago, indicated the same conclusion reached by Brady, that for light-load densities, excess transformer capacity is a cheaper means of limiting the voltage dips due to motor starting currents than the installation of unduly large conductors or the use of unduly close transformer spacing. In fact this same condition is true in the case of larger motors on heavier commercial secondaries. It should not be inferred, however, that this means that underloading of transformers in general is desirable or economical. In most cases, in urban distribution, the installation is providing for an increasing load and, although in the original condition with light loads the transformers may be appreciably underloaded, the same installation can take care of the increase up to the point where the load on the transformer reaches its thermal capability.

Since it is costly to replace conductors or to move transformers frequently, the most economical design will be that combination of wire size and transformer spacing which, within the voltage drop limits which have been assumed, will show the least cost over a considerable period of time with increasing load densities, the transformer size at any time being such as to provide adequately for the existing condition.

We also concur most fully with Brady's conclusion as to the advantages of banking transformers. The maximum voltage dips are cut in half by this practice. Although, as he indicates, banking may not be required to meet the 4-volt limit at the higher load densities, it is very desirable to reduce the dip below this amount if possible. Banking accomplishes this. There are also other advantages in banking in the better distribution of the loads among the transformers, leading to economy by higher average loading, and in the appreciable reduction in customer outage. The Detroit Edison Company has followed this practice for a great many years.

Harold Cole (The Detroit Edison Company, Detroit, Mich.): Brady's paper makes some very pertinent conclusions as to the best methods of reducing costs in a part of the distribution system which is an important element in the total cost of most distribution systems. Studies of this kind are very necessary if we are to keep our investment and operating costs at a minimum.

The advantage of banking transformers as an economical means of reducing voltage flicker has been given considerable emphasis in recent years with the more general use of motor-driven appliances. I also would like to point out that, in areas of light-load densities, banking has the further advantage of maintaining higher steady-state voltages in serving large concentrated loads, such as ranges, clothes dryers, and so forth.

It would appear from Brady's discussion of troubles connected with banking of transformers that he is considering only the "loose" banking method with fuses in the secondary mains midway between transformers. He finds it necessary to make two yearly fuse inspections and the replacement of 17 per cent of the fuses per year. This rate of fuse failure would indicate that blown fuses could remain unreplaced for several months, during which time the voltage flicker at the open ends of the secondaries might be double the permissible values, as I am assuming that not all of the fuse blowings were the result of a complete outage of the transformer. It would be interesting to know if the use of bare secondaries had any great effect on the number of fuse blowings. I would think it likely, however, that low-capacity fuses were used and that a large number of fuse blowings were due to load surges.

The method of banking transformers which we have been using for over 40 years may have its faults, but it results in much less frequent fuse blowing. In the past eight years the average rate of secondary fuse replacement in our Detroit district was 1.2 per cent per year. In our practice, there are no fuses in the secondary mains, but secondary fuses are installed in the connection from the transformer to the mains. These fuses are of such size that only secondary short circuits will cause them to blow. In spite of this fact, there were only 45 transformer failures due to overload or short circuit in our Detroit district. This is a failure rate of less than 0.2 per cent of the transformers involved.

In our case very few of the fuse blowings caused customer service outage, and the only interruptions from secondary causes were very occasional outages of a complete secondary bank, most of which occur in banks consisting of a few small transformers. As Brady points out, irregular platting of many residential areas sometimes makes it impossible to do any banking, and often makes it difficult to get the best conditions for solid banking, as proper arrangement of primary mains is essential to good performance. Where conditions are favorable for its use and it is properly maintained, a high degree of continuity is possible with solid banking with no increase in cost at least over a radial secondary system.

M. G. Leonard (Westinghouse Electric Company, Sharon, Pa.): This paper emphasizes the importance of quality of service as a factor of the design of a distribution system. We agree that this consideration is an important factor in laying out such a design.

Brady shows that, if a quality standard is set up on a basis which appears to be adequate, then the thermal capacity of the transformer tends to disappear as a design limitation. This is, no doubt, true for the assumptions made. We have some general questions however, in regard to these assumptions. In particular we would like to ask:

1. Are the calculations based on the performance of present-day distribution transformers? We have a line of transformers, for example, which are specifically designed for operation by copper temperature. In these transformers, the impedance drop has been kept to a low value. The regulation at full load and 90 per cent power factor is in the range of 2.1 to 2.7 per cent. At the low limit of 22 per cent load, which Brady mentions, this would result in only 1/2-volt drop in the transformer which seems to be a very small value.

2. A second question relates to whether there are not likely to be some conditions of abnormal loading which make copper temperature an important limitation. We believe such conditions should be considered even though they are not included in the system design. For example:

a. Excessive loads caused by peak demand or by faults on the secondary might be sufficiently probable to justify protective equipment on the transformer. The best way to obtain such protection is to use a circuit breaker, thermally co-ordinated with the transformer design.

b. Even though the system is initially laid out on a conservative basis as proposed by Brady, load growth may result in conditions which endanger the transformer, unless the thermal capacity limitation is recognized. Dangerous thermal conditions may not be known in time to permit adding or replacing a transformer before damage results.

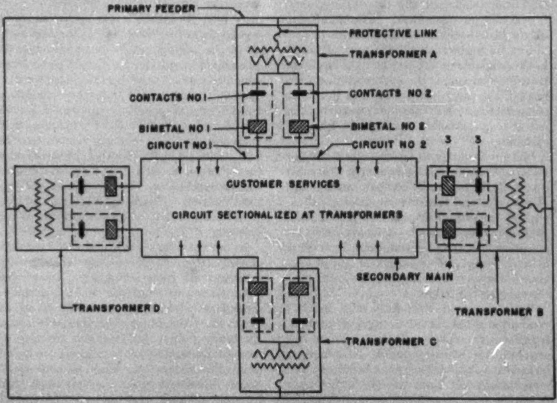
We were particularly interested in the section of this paper dealing with banked transformers. Brady quite properly includes the cost of inspection and fuse replacement in his calculation of the most economical system for a specified quality of service. We would think that two inspections per year, plus 17 per cent fuse replacements, is a very generous estimate. He mentions the use of circuit breakers as a possible alternate, but does not carry this proposal any farther.

We have done a considerable amount of work on this subject, with a view to finding a practical and economical way of co-ordinating the circuit breaker with both the transformer characteristics and secondary service requirements. Several arrangements have been designed and tested. Based on this study, we have developed a system which affords a simple and economical solution to the problem. This system is shown diagrammatically in Figure 2 of the discussion.

Note that circuit breakers are built integrally with the transformers, and connected so that any section of circuit can be isolated by the tripping of adjacent circuit breakers. Thermal setting is adjusted to the capacity of the transformers. Thus we obtain protection for the secondary lines and for the transformer as well.

In case an outage does occur on this system, service can be restored merely by resetting the circuit breaker. Since the total kilovolt-amperes of the bank is relatively large (compared to a radial system) and all of the transformer capacity is available before the circuit breaker trips, many faults can be burned clear, and hence the number of outages is reduced to a minimum. This is, of course, also true of a fused system, except that if fuses are applied to protect the transformer on long-time loads, they do not make the full transformer capacity available for short-time loads.

Figure 2. Banked secondary system with circuit breaker integral with transformers



W. T. Brown (Philadelphia Electric Company, Philadelphia, Pa.): The secondary system is comprised of distribution transformers, secondary mains, secondary branches, and customer services. The design problem is, therefore, to obtain a combination of these elements to supply the secondary load at minimum over-all cost for fixed allowable voltage loss, (steady or flicker) in the secondary system.

Although the optimum loading of distribution transformers and secondary wire depends directly on the allowable voltage loss in the secondary system and the load density in the territory served, the optimum co-ordination of transformer size, secondary wire size, and transformer spacing can be shown to be essentially independent of these factors.

The best wire size for a given transformer size is essentially attained when the increased annual cost of a larger wire size per volt improvement thereby obtained, is just equal to the increased annual cost of a larger transformer size per volt improvement. Any other combination such as smaller transformer size and larger wire size required to remain within the permissible voltage loss limit, whether it be 5 per cent or 10 per cent will be more expensive. The annual saving due to a smaller transformer size would be more than offset by the annual cost of the larger wire. The cost of voltage improvement by increasing either the transformer size or the wire size is inversely proportional to the load supplied. Therefore, the economic co-ordination of wire size and transformer size is independent of load density except as it is somewhat influenced by annual copper loss evaluation.

The best transformer spacing for a given transformer size is also essentially attained when the increased annual cost of transformer capacity due to closer spacing per volt improvement thereby obtained, is just equal to the increased cost of a larger transformer size per volt improvement. Any other combination such as smaller transformer size and less transformer spacing required to remain within the permissible limits of voltage loss, would be more expensive. The annual saving due to the smaller size would be more than offset by the increased annual cost of the greater number of transformers to supply the area. The cost of voltage improvement by reducing the spacing of transformers is also inversely proportional to the load density and, therefore, proper spacing of transformers of a given size becomes independent of load density except as is slightly influenced by annual loss evaluation.

After the proper economic co-ordination of transformer size, transformer spacing and wire size has been determined according to the foregoing principles, then the particular ideal combination of secondary elements to serve a given load density within the permissible voltage loss can be determined. The particular combination to satisfy the given load conditions will therefore vary with the voltage loss permitted by the particular utility. On the other hand, the economic co-ordination of the elements to make up a particular ideal combination will vary essentially with the relative annual costs of the secondary elements and power factor of the load, but is essentially independent of the allowable voltage loss.

These fundamentals are not in variance with the author's paper. They indicate that although his analysis is based on an allowable 6.6-volt loss, the paper has general interest and broad implications.

Chase Hutchinson (Ebasco Services Inc., New York, N. Y.): Economic studies of transformer–secondary conductor which are a part of radial overhead systems are informative and often useful in guiding the operation of distribution systems. However, the choice of limiting conditions and premises may involve judgment and opinion, and it is in this respect that the writer disagrees with some of the conclusions of this otherwise excellent paper.

Banking of secondary systems to reduce flicker and losses, while not wholeheartedly accepted by the industry, is well known and has proved its value in many situations. Further application should be encouraged.

The use of aluminum conductor in lieu of copper, under present price conditions, will produce either a lower initial cost or a lower loss cost. Thus savings may either be taken immediately as a reduction in capital cost or over a period of time as a reduction in cost of losses. Under such conditions use of aluminum for secondary overhead conductor will no doubt expand considerably when the metal becomes more generally available.

Limiting noncyclic decrease in voltage with application of a 20-ampere 60-per cent power factor (lag) 115-volt load is taken as four volts. In the writer's opinion this value is too low and will result in unnecessary use of transformer capacity. This opinion seems to be borne out by the authors proposed use of maximum transformer loading of 80 per cent of rating in light density situations. Under a growing load condition, such a transformer might be loaded initially to values in the range of 40 to 60 per cent of rating. Thus acceptance of the values cited might mean doubling or tripling transformer capacity in the lighter density situations. Generally such situations can least afford the added expense.

The solution seems to lie in the acceptance of a more realisitic value for noncyclic decrease in voltage. Surveys in one area in which service is generally considered satisfactory indicated a value in the region of 10 to 12 volts to be reasonable. When such sudden decreases in voltage were in the range of 14 to 20 volts service was generally considered unsatisfactory.

With respect to Figure 2 of the paper the 10-kva transformer curve indicates the transformer secondary combination has an economical load for satisfactory service of 80 per cent of transformer rating and costs about $57 per year per thousand feet and has an economical load of 230 per cent of transformer rating. Does this mean that the 10-kva transformer installed with number 0 aluminum and a load density of 10 kva per thousand feet would not be loaded in excess of 8 kva? Or does it mean that where density is 10 kva per thousand feet nothing less than 10-kva transformers would be used initially, and as load grows these transformers would be loaded to as much as 140 per cent of rating before steps are taken to reduce the transformer load?

The assumption that secondaries are straight-line 2-way feed represents an extreme condition from the flicker and voltage drop standpoint. In many situations such a secondary layout is used commonly while in others a more complicated layout is attractive. Consider the case where secondary branches in three directions a few spans from transformer as indicated in Figure 3 of the discussion. Here flicker may be much less of a problem than indicated in the paper.

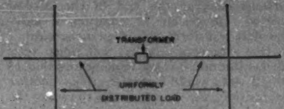


Figure 3. Branched secondary

Charles Dunn (Bonneville Power Administration, Portland, Oreg.): The paper by Brady has some good ideas, but the main criticism of this paper is that it is too specific in its assumptions and cannot be applied to most other systems because of this fact. For one thing, the load assumptions are altogether out of line with the loads which we have in the Pacific Northwest. Brady assumes the load density of 10 kva for 1,000 feet. This is very light loading for our distribution systems in this area. It is not uncommon to have loadings of five to ten times the values given by Brady, especially where house heating loads are involved.

Another assumption of Brady's is that transformer loading is limited to maximum of 140 per cent of name-plate rating. This is obviously a very conservative assumption, particularly in view of the loading which distributors have had to place on transformers during the winter peaks for short-time operation. Utilities in the Northwest believe this figure should be 150 to 175 per cent for short-time loadings.

Brady evaluates losses at certain specific figures which would only apply on his own system. Different figures would have to be used on the Northwest which could change the entire conclusions of his paper. We do not believe that bare aluminum without steel reinforcing should be used as a secondary conductor due to operating difficulties caused by burndowns.

M. B. Elton (Bonneville Power Administration, Portland, Oreg.): Brady states that "most of the flicker voltage drop resulting from the starting of small motors occurs in the distribution transformers and the secondary conductors."

Most of this flicker will be found to occur due to inadequate dwelling wiring over which the utility has little control, if any. Outside of the dwelling, the average allowable variation, in most cases, in the voltage from minimum to maximum will be as follows:

Service = 12.5 per cent or 1.2 volts
Secondary = 37.5 per cent or 3.6 volts
Transformer = 37.5 per cent or 3.6 volts
Primary = 12.5 per cent or 1.2 volts
Total = 100 per cent or 9.6 volts = (8 per cent for State of Washington for towns of 15,000 or more population)

In connection with the "choice of conductor for new systems" Brady speaks of the merit of using bare conductors because "weatherproof covering is an unnecessary luxury." It is true that, from a safety standpoint, the covering of most "weatherproof wires" is very inadequate and even constitutes a potential hazard, particularly if the wire drops to the ground and the unsuspecting public contacts the wire thinking it safe because it has a covering. However, most city ordinances still require weatherproof wires within city limits. Before bare wires could be used, therefore, the city ordnances would have to be changed. This would be a great step forward in permitting more modern engineering and operation practice within urban areas.

This paper contains a very logical approach to the growing problem of reducing voltage flicker due to small motors and to the most economical use of transformers on a network secondary system.

A. Streiff (Portland General Electric Company, Portland, Oreg.): The load density of this company varies from 50 to 100 kw per 1,000 feet in our residential district, and this occurs in the district with people of limited means as well as in our higher class districts. Due to our present rates, most of the people can afford range and water heater service and use electric heat to supplement other forms of house heating. There are also many houses which are electrically heated, and more would be totally electrically equipped if material and electrical power were available.

Due to the foregoing conditions we plan on loading our transformers about 150 per cent in the winter time as the load drops to approximately half this amount during the summer months. Practically all our transformer failures occur during the coldest days of the year.

Most of our secondary systems are radial although we bank two or more transformers together through secondary fuses. We have a number of banked secondary systems using the double circuit breaker current-protected transformers (Westinghouse type *CPB*) which have recently been installed, and which have given us satisfactory service to date.

Most of the secondary system consists of number 4 copper wire, but where the load density is large we use number 1 copper wire in the hot wires and number 4 copper wire in the neutral position. We have not been inclined to use aluminum wire in the more heavily loaded districts and have confined the use of aluminum wire to the rural districts.

However, within the past year we have used approximately 15,000 pounds of number 4 weather-proofed aluminum for service conductors.

Bryce Brady: Seelye has stated one of the conclusions so neatly that I would like to repeat it . . . "for light-load densities excess transformer capacity is a cheaper means of limiting the voltage dips due to motor starting currents than the installation of unduly large conductors or the use of unduly close transformer spacing."

During the war, heavy overloading of distribution transformers was practiced at all load densities. This undoubtedly helped the war effort by conserving copper and steel. Transformers are now more readily available and it appears timely that transformer sizes should be determined entirely in accordance with over-all economy.

Hutchinson asks, in regard to Figure 2 of the paper, if nothing smaller than 10-kva transformers would be used to serve a load density of 10 kva per 1,000 feet. The answer is yes, because the use of smaller transformers results in higher annual cost under the premises of this study.

Campbell asks if the initial installation of 15-kva transformers would not be more economical than 10-kva transformers, if the cost of future replacements were less than the accumulated difference in annual cost. The answer might be yes if the engineer could be certain larger transformers in the same locations would be the most economical arrangement at the end of the 13-year period. Respacing or addition of intermediate transformers is often economical.

One discussor thinks that four volts flicker limitation is not realistic and that 10 to 12 volts would be satisfactory; another states that it is very desirable to reduce the dips below four volts if possible. This divergence of opinion among utility engineers may indicate the need for further investigation of the border line between satisfactory and unsatisfactory service, taking into consideration both the magnitude and the frequency of occurrence of voltage dips in residential areas.

Brown's statement as to the independence of secondary wire size and load density is corroborated by Figure 5. If a median is drawn between the radial and banked curves, number 4 copper and number 0 aluminum conductors are more economical, with minor exceptions, than either larger or smaller conductors throughout the entire range of load densities studied.

As surmised by Cole, our company uses the largest size of secondary fuses at the midpoint between transformers, which will assure short circuit protection. We have not used solid banking because of fear of cascading, but from Cole's remarks such fears may not be justified.

The comments of Dunn, Elton, and Streiff, all located in the northwest, emphasize the divergence of load and operating conditions throughout the nation. The conclusions of the paper are valid where the 21 premises listed in Appendix are tenable. In other locations, the methods used in the study may be utilized with appropriate premises.

Commutation of D-C Machines and Its Effects on Radio Influence Voltage Generation

D. P. MOTTER
ASSOCIATE AIEE

FOR SEVERAL years the generation of radio influence voltage by rotating electric machinery has presented problems in radio frequency transmission and reception. This has been true particularly on aircraft. Radio communication, navigation, and other necessary radio and electronic equipment, along with many rotating electric machines are needed to perform various duties in attaining and sustaining flight and accomplishing the mission of the flight on present-day aircraft. Heretofore, the design of machinery has progressed with little or no thought toward reducing the radio influence voltage generated. Consequently, as aircraft functional performance necessitated more electric machinery, the problem of reducing radio influence voltage generated by the electric machinery resulted in the application of suppression harnesses in the form of radio frequency filters applied to almost every machine. With small d-c machines, satisfactory suppression harnesses often demand an overbearing weight and space requirement on the aircraft in proportion to that of the machines themselves.

In attempting to reduce the necessity of suppression harnesses, it is therefore of great value to study the basic causes of radio influence voltage generation in rotating electric machinery and attempt to reduce the radio influence voltage through design changes in the machines.

The Problem

It is of general knowledge to those who have worked with radio influence voltage generation in rotating electric machines, that radio influence voltage is generated as a result of passing a direct current from a stationary surface (such as a brush) to a revolving surface (such as a slip ring). The radio influence voltage generated under these conditions is considered random in character. The transient voltages generated do not reoccur in a definite pattern, or at a definite repetition rate and cannot be synchronized on the screen of an oscilloscope.

The magnitude of the conducted radio influence voltage measured across the brushes of a d-c commutating machine is often much greater than that measured across slip-ring brushes under identical test conditions. Oscillograms taken across the brushes of a d-c commutating machine indicate the predominance of transients reoccurring in a definite pattern and at a definite repetition rate.

The problem, therefore, is to determine the cause of these repetitive transients and to determine the significance of their possible reduction or elimination in reducing the radio influence voltage generated.

Selection of Machine for Tests

From a group of 30 d-c motors, generators, and dynamotors currently applied to United States military aircraft, a certain dynamotor was selected for the detailed tests. The reason for selecting this particular unit is that the radio influence voltage measured across the brushes of the high-voltage winding under normal operating conditions exceeded the radio influence voltage measured across the same brushes passing the same total current through a slip ring (of same diameter and peripheral speed) by a larger factor than any of the group of over 30 machines comparably tested. In making the selection of the test machine in this manner the effects of the repetitive type transients associated with commutation of current can be analyzed more clearly.

Curve "A" on Figure 1 shows the radio influence voltage measured across the two commutator brushes of the high-voltage winding of the test dynamotor. The machine was operated at rated speed, rated voltage, and load current.

Curve "C" on Figure 1 shows the radio influence voltage measured across the same two brushes riding on a slip ring. For these tests the same total brush current was supplied by batteries. All other test conditions were the same as those while making the tests on the commutator, including total brush current, peripheral speed, brush pressure, and brush-to-brush holder clearance. The data on curve "C" coincide with data taken across the brushes on the commutator with all commutator bars short-circuited, field poles removed, the same total brush current supplied by batteries, the same peripheral speed, and all other test conditions identical.

Test Conditions

The armature of the test dynamotor was driven at rated speed by a separate motor. The motor winding of the dynamotor was not used because the radio influence voltage generated in the motor winding would be coupled into the wind-

---

Paper 49-28, recommended by the AIEE rotating machinery committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted November 17, 1948; made available for printing December 27, 1948.

D. P. MOTTER is a design engineer with the General Electric Company, Fort Wayne, Ind.

This investigation was made by the author while engaged as a development engineer in the general engineering and consulting laboratory of the General Electric Company and under contract with Air Material Command of the United States Air Force, to which the author expresses his indebtedness for permission to submit this paper, and to C. M. Foust and C. W. Frick of the General Electric Company for their aid and general supervision in the investigation.

Figure 2 (above). Brush to brush oscillogram, 1/6 revolution, normal brushes

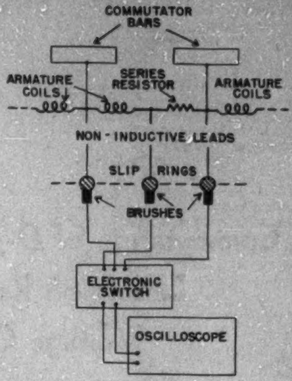

Figure 3 (right). Schematic diagram for measuring coil current and voltage simultaneously

ing under investigation. The shunt field was excited by batteries to provide rated output voltage, and the armature was loaded to rated load current by resistors. The brushes were removed from all commutators of the armature windings except the one under investigation which requires only two brushes. The brushes used for all tests were well seated and run in until all of the brush face area was polished and the commutator film build-up apparently at equilibrium. The same brush holders, nominal brush pressures, and brush-to-brush holder clearances were used in all tests. All radio influence voltage measurements (in microvolts) were made with a standard radio noise and field strength meter connected across the two commutator brushes, and were calibrated with a standard sinewave generator. All tests were made within a double screen shielded room.

Repetitive Transients Present

By connecting a cathode-ray oscilloscope across the two brushes on the commutator of the armature winding under investigation (with negative brush grounded), the presence of transients occurring at a definite repetitive rate is shown. Figure 2 is an oscillogram made under the test conditions stated before while employing the brush grade normally used on this winding of this machine. The radio influence voltage generated at frequencies between 0.16 to 20 megacycles is shown on curve "A" of Figure 1. No visible sparking could be seen during these tests, even in total darkness.

Many other standard grades of brushes were tested with approximately the same results in magnitude of repetitive transients as well as magnitude of radio influence voltage measured.

By properly synchronizing the sweep of the oscilloscope with armature rotation by means of a capacitive pick-up mounted on the revolving armature shaft, it was shown that the number of transients present is equal to the number of commutator bars multiplied by the number of armature circuits for each revolution. This indicates that a transient occurs each time an armature coil is commutated, but does not indicate at what time during the commutation period these transients are produced. It was therefore necessary to determine the differential armature coil currents and voltages during the commutation period of the armature coils.

Measurement Technique for Commutation Evaluation

To observe instantaneous values of armature coil voltage and current simultaneously, three slip rings were insulated from and mounted on the armature shaft between the commutator and bearing. These slip rings were connected to an armature coil by short noninductive leads and to a cathode-ray oscilloscope through slip-ring brushes and an electronic switch as shown in Figure 3. Thus, instantaneous armature coil voltage is measured across one armature coil and the instantaneous coil current is measured across the resistor in series with the armature coil.

The resistor in series with an armature coil on this diagram was a short piece of twisted resistance wire. It was mounted circumferentially along the armature shaft to eliminate the possibility of voltage being induced in it as a result of cutting the fringing flux of the poles. The impedance as well as the d-c resistance of this series resistor was very small in comparison to that of the armature coil so that dynamic balance of the armature circuits was not affected.

It has been determined that certain silver-graphite brushes generate less radio influence voltage on a slip ring than many other standard grades of brushes under the same conditions. These silver-graphite brushes were used on the slip rings and were specially selected and fitted in their brush holders to minimize the possibility of radio influence voltage generation from this source.

Sources of Transients

Figure 4 is a voltage and current oscillogram of one armature coil for approximately one armature revolution while employing the regular brushes on the commutator. The presence of transients on both the current (*I-I*) and voltage (*E-E*) traces is shown. The magnitude of the step (*X-Z*) in the voltage trace during the commutation period is equal to the *IR* change as a result of the change of direction of current of the armature coil under investigation.

Figure 5 is an oscillogram showing the

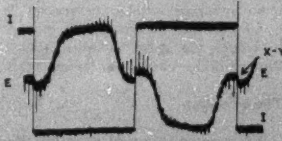

Figure 4. Voltage and current oscillogram, one armature coil, normal brushes

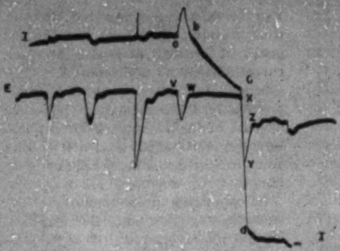

Figure 5 (left). Voltage and current oscillogram during commutation period, one armature coil, normal brushes

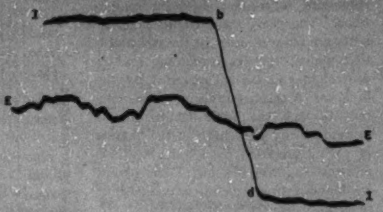

Figure 7 (right). Voltage and current oscillogram during commutation period, one armature coil, developmental laminated brushes

same voltage and current traces as Figure 4, but is expanded sufficiently along the *Y* axis and greatly along the *X* axis to show more detail of these traces during the commutation period of the armature coil under investigation. The sweep on this oscillogram is conventionally left to right. The points *b* and *d* represent the beginning and end of the commutation period respectively. The transients *X-Y-Z* appearing on the coil voltage trace coincides (in respect to time) with the relatively rapid rate of coil current change between points *c* and *d*. This was true for each armature coil investigated. It was therefore established that these transients were produced at the ends of the commutation periods of the armature coils.

It is interesting to note on Figure 5 that the transient (*V-W*) produced at the end of the commutation period in the coil immediately adjacent and in advance of the coil under observation produces a transient current rise in the coil under observation between the points *a* and *b*. The current in the coil under observation tends to oppose the change in current in the other coil since both coils are in the same armature slot and inductive coupling is relatively close.

There is a difference of induced voltage in the last coil in an armature slot with respect to the first coil in the next armature slot due to their circumferential position differences in the fringing flux field. There are three coils per armature slot on the test machine and the span of the brush is one commutator bar. Therefore another transient is produced at the end of the commutation period of every third coil. This transient is superimposed on the transient regularly appearing at the end of the commutation period and explains the greater magnitude of every third transient (*t*) shown on Figure 2.

Brush-to-commutator discontinuities of contact will produce objectionable transients either random or repetitive in character, depending upon the causes of the discontinuities. In the tests described in this paper, no such discontinuities were in evidence.

Figure 6. Brush-to-brush oscillogram, 1/6 revolution, developmental laminated brushes

Commutation with Standard Brushes and No Interpoles

Machine and brush designers are well acquainted with the problems involved in making it possible for the brush to largely control coil current reversal in d-c machines.

This is particularly a problem in the design of machinery for aircraft application wherein weight and space considerations are stringent. These considerations many times limit the possible employment of interpoles and prohibit their use on dynamotors. In addition, high contact drop brushes adversely affect machine efficiency.

On d-c machines, circulating current across the brush face is mainly affected by either or both the self-induced voltage of the armature coil opposing current change during commutation; and induced voltage in the armature coil during the commutation period resulting from the shift of the magnetic neutral with change in armature current. If either or both of these induced voltages are of sufficient magnitude, the brushes lose a large share of their control over coil current reversal. Circulating currents flow in the coil-bar brush-bar coil circuit, the rate of coil current change is not linear, and the greatest rate of coil current change occurs late in the commutation period as exemplified in Figure 5. The brush cross-face resistance is considerably lower than the contact resistance, and in many cases has relatively little significance in limiting the circulating currents. Of all the standard grades of brushes tested on this test machine, including brushes rated at "very high contact drop" as well as "very low contact drop," none showed marked improvement in commutation over the brushes normally used.

Commutation with New Laminated Brushes

New laminated brushes have been designed which improve commutation and reduce radio influence voltage generation over a rather wide range of armature currents.

With the new laminated brushes, the commutation of current in an armature coil depends largely upon the increase in resistance of each brush lamination as the commutator bar progresses from the leading edge to the trailing edge of the laminated brush. The thickness of each lamination in the brushes used on the test machine is equal to or less than the thickness of insulation between two adjacent commutator bars. Each brush lamination is insulated from all others (as well as from the brush holder) except at the pigtail end of the brush. A simple sketch of this brush structure is shown in Figure 8. As a result of this design the circulating current across the brush face must flow through the entire length of two brush laminations whose combined resistances are considerably larger than the resistance across the face of a nonlaminated brush or of a laminated brush not

Figure 8. Developmental laminated brush showing division of current during commutation

employing insulation between laminations. Therefore, these circulating currents are reduced early in the commutation period, thereby promoting greater control of coil current reversal by the brushes. A relative division of line current through the brush laminations is represented by the length of the vectors in each lamination on Figure 8. This more or less forced division of line current is conducive to a more linear coil current reversal.

Figure 6 is an oscillogram taken across two developmental laminated brushes applied to the test machine. The absence of transients is noted. Test conditions were identical to those in making the oscillogram of Figure 2 with the normal brushes.

Figure 7 is an oscillogram showing the expanded voltage and current traces of an armature coil during commutation while employing the developmental laminated brushes. The rate of change in coil current is nearly linear during the commutation period (*b* to *d*), and absence of transients on both the current and voltage traces is noted. Test conditions were identical to those in making the oscillogram of Figure 5 with the normal brushes.

Radio Influence Voltage Reduction

Curve "B" on Figure 1 shows the magnitude (in microvolts) of the radio influence voltage generated while employing the developmental laminated brushes on the test machine over the frequency range 0.16 to 20 megacycles. The data for this curve were recorded during the time the oscillograms were taken, and coincides with data taken in other tests at frequent intervals during continuous operation of over 150 hours. The average radio influence voltage reduction provided by the laminated brushes as compared to the brushes normally used on this machine is shown in Table I.

Commutation Period Transposition

Figure 9 shows the change in magnitude of the radio influence voltage generated at 0.16 megacycle as the commutation period is shifted with respect to the magnetic neutral while employing standard grades of brushes (curve "B") and the laminated brushes (curve "A") on the test machine. For these tests a special vernier brush shifting mechanism was employed. The physical mid-point between the two field poles is marked zero degrees. Sufficient run-in time was permitted to assure the best possible brush seating for each test point. Load current was adjusted to rated load with brushes set in the best commutating position (27 degrees) as determined by oscillograms similar to Figure 5.

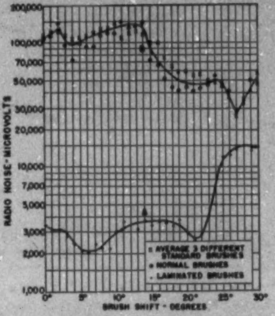

Figure 9. Comparison of laminated brushes (A) to normal and other standard brushes (B), brushes shifted with respect to magnetic neutral

Table I

Frequency Range, Megacycles	Average Radio Influence Voltage Ratio Normal		Laminated
0.16 through 1	12	to	1
1 through 5	6	to	1
5 through 20	2	to	1
0.16 through 20	10	to	1

The brush position for commutating full-load current at rated voltage at the minimum induced armature coil voltage position is at 22 degrees on Figure 9. This was determined by shifting the brushes into a position wherein the current trace started to cross the voltage trace at minimum coil voltage. Best commutation and minimum radio influence voltage generation occurred five degrees in advance of this position (27 degrees) while using standard grades of brushes as shown on curve "B."

From the radio influence voltage data and correlated oscillograms it was established that with standard brushes there is a finite position of the commutation period with respect to the magnetic neutral at which best commutation and minimum radio influence voltage is produced.

Curve "A" on Figure 9 shows that the radio influence voltage generated while using the laminated brushes is essentially constant over a 22 degree range of transposition of the commutation period behind the minimum induced armature coil voltage position. Oscillograms indicated better commutation with the laminated brushes over this wide range of commutation period transposition than the best commutation position with the standard grades of brushes. It is also shown on curve "A" that the radio influence voltage generated increases rapidly with transposition of the commutation period in advance of the minimum induced armature coil voltage position, and oscillograms indicated poor quality of commutation.

By comparing the performance of the laminated brushes and the standard brushes in this manner it may be concluded that better commutation will result and radio influence voltage will be reduced over a wider range of armature currents by utilizing the laminated brushes.

Design of Effective Laminated Brushes

The laminated brushes used on the test machine are made of four laminations of equal size, but each of different resistivities and total resistances from brush face to pigtail as shown in Table II.

Four other laminated brushes were designed identical to these brushes in every respect except resistivities of the laminations, and were tested on the test machine. In all designs wherein the leading lamination resistance was the same as shown in Table II, but the trailing lamination resistance was lower, and the second and third laminations of lower intermediate resistances, considerably less commutation improvement and radio influence voltage reduction was provided. From these tests it is concluded that for a given machine design there is a finite laminated brush design to provide an optimum performance by this method. The machine design factors most affecting the design of laminated brushes are those bearing upon the aggravation or amelioration of circulating current in the brush-commutator bar-armature coil-commutator bar-brush circuit. Other major considerations are the magnitude of armature current in various phases of operation (and including starting), current carrying capacity of brush laminations, whether or not interpoles are incorporated in the design, and

Table II

	Resistivity, Ohm-Inches	Total Lamination Resistance, Ohms
Leading lamination	0.000016	0.00192
Second lamination	0.0007	0.084
Third lamination	1.3	150.0
Trailing lamination	8.0	480.0

whether the machine is reversible or unidirectional.

Insulation between laminations must be provided to reduce circulating current across the brush face and be of such material as to prevent conducting brush material from depositing on it at the brush face and producing a low resistance path across the brush face.

Limiting the maximum thickness of each brush lamination to the thickness of insulation between commutator bars is essential in the design of effective laminated brushes for the test machine. This design requirement may not be necessary to provide optimum performance in applications on other machines.

Theoretically, an infinite number of brush laminations are necessary to eliminate transients appearing at the transition of one lamination to the next lamination. Actually, the machine constants and the economics of the design and manufacture of the brushes are the determining factors.

All short-circuit paths between brush laminations (except at the pigtail end of the brush) must be eliminated. This necessitates insulating the brush from the brush holder, or making the brush holder of insulating material.

By making each conducting brush lamination of the same material, and inserting the necessary resistances in each lamination at the pigtail end of the brush, the optimum performance characteristics of the brush may be realized over the entire life of the brush.

Conclusions

1. One of the main causes of radio influence voltage generation in d-c rotating machinery is transient voltages produced during commutation.

2. The magnitude of the transients and of the radio influence voltage generated is dependent upon linearity of armature coil current reversal.

3. Black band commutation is no assurance of the best quality of commutation to minimize radio influence voltage generation.

4. Where interpoles are not employed, there is a finite armature current at which commutation is of better quality and minimum radio influence voltage is generated while using standard brushes.

5. Developmental laminated brushes can improve linearity of armature coil current reversal and provide an appreciable reduction of radio influence voltage generation over a rather wide range of armature currents.

Discussion

C. W. Frick (General Electric Company, Schenectady, N. Y.): It has been known since the early development of radio communication that commutator motors and generators produce electric disturbances which may affect radio reception adversely under some conditions. While the presence of these disturbances has not been ignored, the common attitude has been that nothing could be done to prevent their occurrence. There were several reasons for this attitude. One reason was that the usual means for obtaining acceptable commutation failed to eliminate the disturbances. Another reason was that the earlier problems of radio interference were concerned largely with reception of standard broadcast signals. In that case it was usually an easy matter to eliminate or reduce the effects of the disturbance by adding a small capacitor to the commutator machine. This treatment does not attempt to deal with the cause of the disturbance and is known generally as suppression.

As pointed out in the paper, it was the use of radio communication in aircraft that brought attention to the need for a fundamental approach to the problem of reducing the radio influence of commutator machines. One of the accomplishments of the investigation reported is shown effectively by Figures 5 and 7 of the paper. Figure 5 shows armature coil current and voltage for a machine as originally tested. Current reversal instead of being smooth is characterized by a sudden jump at the end of the commutation period. Figure 7 shows the same current and voltage after means were applied to cause the current in the coil to reverse smoothly. In this case the treatment was the application of a specially-designed brush. A marked reduction of the transients in the voltage wave is apparent. The effectiveness with respect to radio influence is demonstrated by test with the radio noise meter which shows a 10-to-1 improvement over a widely used part of the radio spectrum. It is significant that the improvement is brought about by the treatment of conditions which cause the disturbances, not by suppression of disturbances after they have been produced.

This paper is a useful contribution to the attack of the problem of reducing the radio influence of machines of this type. Of course finding out how to do it is only part of the final answer. The design of commutator machines of many different sizes and performance characteristics has been developed over a period of many years. Changes which are introduced for a specific purpose need to be evaluated with respect to their effects on other performance characteristics. In order to apply successfully the ideas set forth in the paper such evaluations must still be made.

E. H. Myers (Westinghouse Electric Corporation, East Pittsburgh, Pa.): 1. This paper is one covering a subject on which very little is known, but one which is becoming increasingly important each year. This is particularly true on machines for naval and military use.

2. Most of our experience on the investigation of radio interference has been on much larger machines than those described by Mr. Motter. We were particularly interested in comparing the data presented in the paper with that which we took on much larger machines.

3. One rather interesting point is that the peak voltage given for the test machine with normal breakers was 220,000 microvolts, which was reduced to 13,000 microvolts by the use of a special laminated brush. From the paper it appears that the machine used was a small size noncommutating pole unit. We normally would expect such a machine to have rather easy commutating problems, due to the low reactance voltage and high armature resistance inherent with a very small machine. Mr. Motter confirms this somewhat by stating that no visible sparking could be seen during the tests. On a 300-kw 240/120-volt 1,200-rpm generator on which we carried out tests a few years ago, the peak radio noise without suppressors and with standard brushes, was about 26,000 microvolts.

4. A comparison of these data seems to indicate that the commutating poles on the larger machine on which we would expect to have more severe radio interference than on a smaller machine, have performed about the same function as the laminated brush on the smaller unit, that is, they force the current during reversal to approach a straight line variation.

5. We would like to know if Mr. Motter has had experience with laminated brushes on larger machines with commutating poles? If so, is the reduction as pronounced as on this small machine, and what reduced noise advantages were gained?

6. The reduced value of radio noise with laminated brushes of 13,000 microvolts as obtained on this small machine is, of course, way above the value normally accepted by purchasers of machines for military use, so that the use of a suppression circuit would be required in addition to the laminated brushes, in many cases. Could Mr. Motter give some information about the proportionate savings in size and weight of the filter by using laminated brushes? Were any data obtained on the basis of thicker laminations, that is, with laminations covering more bars?

D. P. Motter: Mr. Frick's discussion adds materially to the background of this paper, for which the author wishes to express appreciation. The author agrees that further evaluations need to be made in order to successfully apply the ideas set forth in the paper.

Mr. Myers' questions are answered below in the order in which they were presented in the discussion:

In items three and four of Mr. Myers' discussion it is assumed that the discussion refers to the repetitive type of transients as the cause of more severe radio influence voltage expected from the larger machines employing interpoles, and not the random type of transients which may be significantly greater in magnitude as associated with larger brush-face areas and at higher nominal current densities. It is true that higher reactance voltage generally associated with the machines of the size mentioned by the discusser do affect commutation. This effect exhibits itself at the trailing edges of the brushes, or near the end of the commutation period, in the form of arcing. In the author's opinion, at least some, if not all, of this electric energy could be absorbed in properly designed brush laminations at the trailing edge of the brushes. Such a design of laminations might require somewhat higher resistances near the main conducting portion of the brush and still higher resistances near the trailing portion of the brush to prevent resistance transitions of great magnitude, and therefore burning, between laminations.

In reference to item four of Mr. Myers' discussion, there is a question in the author's mind as to whether interpoles can be designed and constructed practically and economically to provide the necessary control of commutation apparently needed for radio influence voltage reduction.

Since the presentation of this paper at the AIEE Winter General Meeting, the author has had opportunity to evaluate the performance of a set of simple laminated brushes on a 100-kw, 240/120-volt 1,200-rpm d-c generator. These brushes were made up with three-quarters of the thickness (dimension in direction of rotation of commutator) of the brush of nearly the same material as the normal brushes used, and one-quarter of the thickness of somewhat higher resistance brush material at the trailing portion of the brush. Although the brushes did not operate satisfactorily at rated load current of the generator, the brushes operated satisfactorily and showed increased black band width and radio influence voltage reduction at load currents less than rated load current of the generator. With the generator loaded to one-quarter rated load current, and with no radio influence voltage suppression, the average of all readings from brush terminal studs to the grounded terminal frame while employing the simple laminated brushes, was 54 per cent lower than the average of the comparable readings while employing the brushes normally used on this machine. With a considerable degree of suppression, but with all other test conditions as shown, the average of all readings while employing the simple laminated brushes was 43 per cent lower than the average of all readings while employing the normal brushes. These tests covered a frequency range from 150 kc through 20 megacycles. Whether or not a brush of this type could be made that would carry the rated load current of the generator and obtain the same quality of improvement has not been evaluated.

In reference to item six of Mr. Myers' discussion, a careful evaluation of proportionate savings in size and weight of filters by using laminated brushes on a wide variety of machines is not available at this time. It is felt, however, that by reducing the radio influence voltage generation to the magnitude of that of the radio influence voltage generated by the random-type transients not associated with commutation of current, the filter requirement would not be as great. It has been shown that the repetitive type of transients generally are of much higher energy, and consequently are much more difficult to effectively filter than the random type of transients.

In the case of the test machine as reported in the paper, it would have been necessary to use a larger brush holder to evaluate the same number of laminations (with the same resistances in each lamination) but of greater thickness. However, the thought was that where a greater control of the commutation of current was needed (such as in the test machine) much could be gained by limiting the thickness of laminations to a dimension equal to or slightly less than the distance between commutator bars. From recent tests on larger machines employing interpoles it appears that the laminations can be thicker, that is, span more bars where less control of coil current by the brushes is required during commutation.

Performance of Diesel-Electric Rig for Deep-Well Drilling

E. C. CLARK
ASSOCIATE AIEE

B. L. MOORE
NONMEMBER AIEE

Synopsis: The successful operation of a big diesel-electric powered drilling rig has permitted the taking of accurate electrical data during normal deep-well drilling on each of the main motor drives and on the engine-generator sets. This paper presents: A description of the power plant and the main power equipment; an elementary power diagram showing the main d-c circuits; a discussion of the functions of the electrohydraulic governor which regulates engine speed from half speed to full speed; the operation of the rig as seen by the driller who is uninterested in the technical details of the governors and amplidynes; test data taken on the engine-generator sets showing how the governor regulates engine speed and limits engine loading; and test data taken on the drawworks motor, the mud pumps, and the rotary table motors and a discussion of the power requirements of each.

DIESEL-electric barge rig number 29 is one of the most powerful in operation today. The rig combines operating simplicity and flexibility with low fuel cost. Although designed primarily for economical drilling of deep wildcat wells, it is equally suitable for drilling production wells.

General Arrangement

POWER PLANT

The power for the rig is supplied by three 900-rpm 700-horsepower supercharged diesel engines each of which is equipped with an electrohydraulic governor.

Direct connected to each engine is a 500/375-kw 900-rpm 600/450-volt amplidyne controlled main generator. Top-mounted and belt-driven from each of the main generators is a 60-kw 125-volt 1,700/850-rpm auxiliary generator with a direct-connected exciter. Voltage regulators maintain a constant potential of 125 volts over the engine speed range.

DRAWWORKS

The 4-speed drawworks is driven by a 1,000-horsepower 75 degrees centigrade continuous 725-rpm 425-volt motor which has a peak rating of 1,667 horsepower. The drawworks provides step-down gear ratios from the motor shaft to the drum shaft of 9.06-1 (low-low), 5.73-1 (high-low), 3.65-1 (low-high), and 2.30-1 (high-high). The drum diameter is $30^{5}/_{8}$ inches.

Assuming that the effective drum diameter is $34^{1}/_{2}$ inches, the maximum hook speed that can be attained in high-high gear with eight lines to the traveling block is 540 feet per minute when the motor is operating at its rated (625 volt) maximum speed of 1,100 rpm. With ten lines to the traveling block, the maximum hook speed is 432 feet per minute.

MUD PUMPS

The two 480-horsepower 55-rpm $7^{3}/_{4}$ by 20 inch mud pumps are V-belt driven by two 500-horsepower 900-rpm 425-volt shunt-wound motors. Each pump will provide a maximum pressure of 1,200 pounds per square inch. The mud mixing pump which provides a maximum pressure of 1,160 pounds per square inch is V-belt driven by 60-horsepower 115-volt 690/1,380-rpm adjustable-speed shunt-wound motor.

ROTARY TABLE

The rotary table is driven by a 300-horsepower 875-rpm 425-volt shunt-wound motor through a 3.84-1 step-down gear. The 1,300-rpm maximum speed (625 volts) of the motor corresponds with a table speed of 340 rpm.

CORING REEL

The coring reel motor is a duplicate of the rotary table motor.

VENTILATION

The drawworks motor, the mud pump motors, the rotary table motor, the coring reel motor, the mud mixer motor, and the main control unit are ventilated by a

Paper 49-121, recommended by the AIEE Chemical, Electrochemical, and Electrothermal Applications Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE South West District Meeting, Dallas, Tex., April 19–21, 1949. Manuscript submitted March 8, 1948; made available for printing February 24, 1949.

E. C. CLARK is with the General Electric Company, Schenectady, N. Y., and B. L. MOORE is with the Humble Oil and Refining Company, Houston, Tex.

Figure 2. The 375-kw main generators and the top-mounted 60-kw auxiliary generators which supply power for rig number 29

central cooling system which is powered by a 30-horsepower 115-volt shunt-wound motor.

AUXILIARIES

The various rig auxiliaries are supplied with power by the three 125-volt d-c auxiliary generators. A list of the auxiliary drives is given in Table I.

Two emergency 9-kw 120-volt d-c engine-generator sets are available, one on the derrick barge and one on the power barge.

Rig Operation

POWER CONNECTIONS

The electric power connections for this rig are shown in Figure 5.

Each generator is provided with an isolating disconnecting switch and four motor selector switches which permit the generator to be connected to any main motor. Magnetic contactors (*H* and *D*) do all the power switching except for initial "set-up" switching. Relaying is provided so that the control switching automatically follows the power switching. When power switching has been properly done, the control circuits will be properly connected. A motor master switch conveniently located controls the operation of each motor regardless of generator selection.

Table I

Number	Motor Rating, Horse-power	Power Requirement, kilowatts	Equipment
1	60	51.0	Mud mixing pump
1	30	26.0	Blower

		10.0	Lights
		16.0	Motor fields
		254.13	Total kilowatts

* 16 kw is sufficient at one time, therefore, peak load is approximately 180 kw.

** Never operates simultaneously with other loads.

Deep-well drilling requires the simultaneous operation of two mud pumps, the rotary table, and the mud mixing pump. The rotary table and the two mud pumps may each be connected to any main generator through their *D* contactors while the mud mixer may be connected to any one of the three auxiliary generators.

The time spent in making a round trip is dependent upon the power supplied to the drawworks. As shown in Figure 5, the entire power output of the three engines may be supplied to the drawworks motor by closing the *H* contactors.

GOVERNOR OPERATION

The unique feature of the power system is the electrohydraulic engine governor. The governor is similar to those being used on diesel-electric locomotives, but it has never before been applied to a diesel-electric drilling rig.

The functions of the governors and associated amplidyne exciters are:

The Control of Engine Speeds

The engines operate over a speed range of 450–900 rpm. The governors permit the engines to operate at the lowest speeds compatible with the load requirements

The Limiting of Generator Loading

The governor limits generator loading to an amount that will not overload and stall the engine under any conditions

The Limiting of the Amount of Fuel Injected

The permissible maximum torque of a diesel engine varies with engine speed. The torque may be limited to the safe maximum value by limiting the amount of fuel injected. The governor limits the maximum amount of fuel that may be injected as a function of engine speed

The Control of Injection Timing

The proper injection timing of a diesel engine varies with speed. The governor regulates the timing as a function of engine speed (motor master switch position)

Figure 3. The driller operating the controls of the drawworks

The Limiting of Generator Currents

Over-current is destructive to d-c machinery because of heating and possible commutator damage. It might be destructive to driven equipment because of the excessively high torques it produces. The amplidyne exciters limit generator currents to safe preset values even though the motors may be stalled

The Control of Generator Voltage

Motor speed is determined primarily by generator voltage. The governor-amplidyne-exciter combination controls generator voltage and engine speed as functions of the position of the driller's master switch.

GOVERNOR CONTROLLED ENGINE GENERATOR CHARACTERISTICS

Test data were taken on one of the engine-generator sets to obtain a volt-ampere characteristic at various engine speeds. The results of this test for engine speeds of 516, 703, and 900 rpm are plotted in Figure 6. The 450-rpm curve is calculated from test data. As the engine speed is set entirely by the position of a master switch, these curves were taken by setting the master switch at several positions and varying the generator loads. In order to understand what the governor accomplishes as far as the speed and torque of the driven motor are concerned, it is necessary to be familiar with the characteristics of a d-c shunt-wound motor. Within reasonable limits,

Figure 4. Rear view of the drawworks showing 1,000-horsepower drawworks motor and ventilating duct on right

the torque of a d-c motor is directly proportional to the current. The speed of the motor is directly proportional to the voltage. Therefore, in a qualitative discussion of motor operation the terms speed and voltage and the terms torque and current may be used interchangeably.

Since all of the curves on Figure 6 are similar, the 900-rpm (engine speed) curve will be discussed only.

As the generator current is increased from zero (point *a*) to 940 (point *b*) amperes, the voltage drops slightly providing a desirable characteristic for stable motor operation. As the engine load increases from zero to full load (point *b*), the governor adjusts the position of the fuel rack so that the speed is maintained at 900 rpm regardless of the load and adjusts injection timing properly for 900-rpm engine operation.

With 940 amperes and 535 volts on the generator the fuel rack is in its limiting position (adjusted by governor as a function of speed) and the engine is fully loaded. A further increase in load will slow down and stall the engine.

When the attempt to further increase the generator load (beyond 940 amperes) is made, the engine slows down transiently as the amount of fuel injected cannot be further increased. The transient decrease in engine speed causes the governor to decrease the voltage and the load on the generator so that the engine accelerates again to 900 rpm with just the amount of load that it may carry at 900 rpm. Thus, as the current is varied from 940 (point *b*) to 1,640 (point *c*) amperes, the generator voltage is reduced by the proper amount to maintain constant load on the engine.

At 1,640 amperes (point *c*) the generator is near its maximum permissible current (rated 833 amperes). Further increase in the generator current causes the voltage to drop rapidly, decreasing the load on the engine. At 1,960 (point *d*) amperes output the generator voltage is zero and the power output from the engine is very small (losses only). Engine speed is maintained at 900 rpm.

The other characteristic curves shown on Figure 6 are similar to the 900-rpm curve.

The dotted, approximately vertical line shows the effect of the governor fuel limit cam. If these diesel engines were constant torque machines, this line would be vertical as constant current output would indicate approximately constant engine torque. However, these engines are equipped with turbochargers which are more effective when the engines operate at a high speed. Thus, as the engine speed increases, the maximum permissible engine torque also increases, giving an increase in engine power which is more than proportional to engine speed.

In order to illustrate the flexibility permitted with diesel-electric drive as provided on this rig, a simple arrangement of one generator supplying one motor is selected. The engine and the motor have identical horsepower and speed ratings of 700 horsepower and 900 rpm. The operation of each will be predicted from the test data on Figure 6.

For the first case, assume that the motor master-switch is in the full "on" position and that the motor torque is varied. The engine will run at 900 rpm. With zero torque on the motor and zero amperes output from the generator, the generator voltage will be 640 volts (point *a*), which will correspond to 150 per cent of motor speed (1,350 rpm). As the motor torque increases to 70 per cent rated torque (900 amperes), the motor speed will reduce to 126 per cent (point *b*) as determined by applied volts. As the torque on the motor is further increased, the speed will decrease but the horsepower output will remain constant at 100 per cent until 127 per cent (point *c*) torque is reached. At this point, current limit is reached and the motor speed will drop rapidly so that the motor will stall at 153 per cent torque (point *d*). When the motor stalls at 153 per cent torque, the generator voltage is practically zero and the generator load consists entirely of losses. Therefore, the engine is almost entirely unloaded. The engine speed remains at 900 rpm since engine speed is a function of master switch position only.

The 900-rpm (engine speed) curve of Figure 6 represents the speed-torque curve of the motor in this example with the abscissa representing motor torque (1,290 amperes = 100 per cent motor torque) and the ordinate representing motor speed (425 volts = 100 per cent motor speed).

The second example assumes a constant torque load on the motor and allows the motor speed to vary under control of the master switch in order to show the relation between motor speed and engine speed. A constant torque load of 50 per cent is assumed which corresponds with 650 generator amperes. In order to show clearly the relation between the engine speed and the motor speed, some of the data presented in Figure 6 are replotted in Figure 7 using different coordinates. Initially the motor speed is zero (point *a*, Figure 7).

As the master switch is moved forward, the speed of the motor increases without affecting the engine speed until the motor is operating at 66 per cent of rated motor speed (point *b*). As the motor speed is further increased, Figure 4 shows that the engine speed is also increased.

When the motor has reached a top speed of 133 per cent (point *c*), the engine speed has increased to 100 per cent. The torque load on the engine has been essentially constant as its speed increased from 50 to 100 per cent.

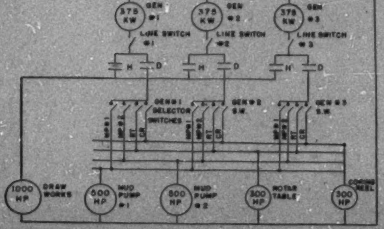

Figure 5 (above). Power connection diagram

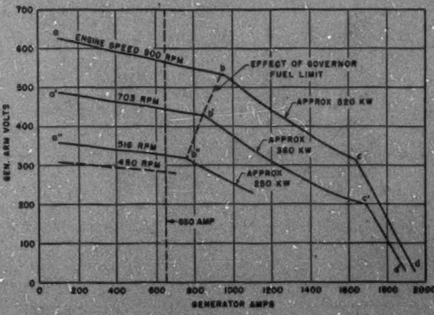

Figure 6 (right). Volt-ampere characteristic of governor controlled engine-generator set

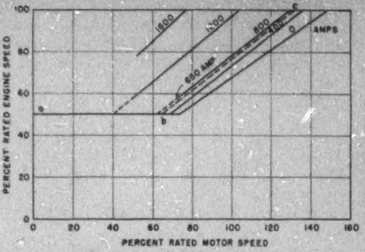

Figure 7. Approximate curve showing motor speed plotted against engine speed

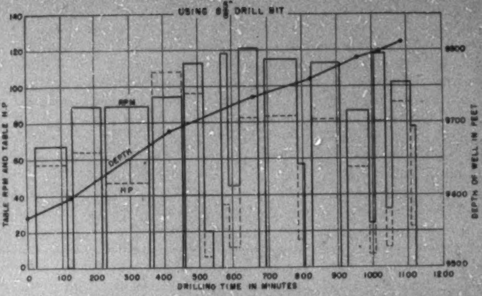

Figure 8. Rotary table horsepower, rotary table speed, and well depth plotted against drilling time

The first example allowed the motor torque to vary from zero to 150 per cent while the engine torque never exceeded 100 per cent. The governor makes it impossible to overload the engine regardless of the wishes of the operator.

The second example showed that as the motor speed was varied from zero to 133 per cent, the engine speed varied from a comfortable 50 per cent to a maximum of 100 per cent. It also showed that when the motor is driving a slow speed load, the engine will be operating at base speed. On a drilling rig, this is a very substantial part of the total operating time, and thus a great many unnecessary engine revolutions are saved.

Operation of the drawworks requires the use of all three generators in parallel for maximum power output. Provision is provided in the control system so this is easily done. Complete control of the drawworks motor, the three generators, and the three engines is from the drawworks master switch.

Operation of Rig by Driller

The only thing that concerns the driller is what happens when he operates the master switches, so it would be well to examine the operation of this rig from his point of view.

In order to start up this rig after a complete shutdown, the driller starts up the diesel engines and throws the switches to put auxiliary power on the lines. Going to the main control board, he may, for example, connect generator number 1 to mud pump number 1, generator number 2 to mud pump number 2, and generator number 3 to the rotary table (see Figure 5). He steps out to his position beside the drawworks and throws the drill-hoist selector switch to the drill position, closing all of the *D* contactors shown in Figure 5.

The rig now is ready to operate and the mud pumps and the rotary table are under control of their own driller's master switches. The mud mixer speed is controlled by its own field rheostat.

The driller need not concern himself with engine speed. He controls the speed of each main motor by its master switch and the engine speed is controlled automatically.

The driller has before him at all times electric meters indicating the speed of the rotary table, the torque of the rotary table, and the current of each mud pump motor.

After drilling for a period of time, the driller will find it necessary to make a round trip for any one of a number of reasons.

He operates the drill-hoist selector switch at the driller's position to close the hoist contactors which connects the three generators in parallel to the drawworks motor. The drawworks master switch has full control of the three generators. (It is not necessary that all of the generators be transferred to the drawworks motor if a different function is desired that requires the use of one. However, in general, all three generators are connected to the drawworks motor for a round trip.)

Starting the first hoist, he throws the drawworks master switch to the full "on" position.

The engines immediately accelerate to full speed and deliver maximum power to the drawworks. The driller does not have to worry about overloading any engine, or the motor, or about load division between engines as this is taken care of automatically by the governor and amplidyne system. When the hoist is completed, the driller stops the drawworks motor and the engines decelerate. The driller breaks the joint in the drill stem with the cathead and steps on the "spinout" switch, which operates the rotary table at a preset speed to unscrew the thribble. He then removes the disconnected thribble and drops the hook for the next hoist.

A drawworks motor ammeter located conveniently indicates to the driller the load on the drawworks motor and helps him to shift gears at the proper time for highest speed operation.

The next hoisting cycle will be exactly like the preceding one, except that the hook speed will be slightly higher. As the load on the hook is decreased, the speed will increase automatically if the driller takes advantage of the constant horsepower characteristic of the system.

If one of the diesels is not in operation at the time of a round trip, only two generators will be assigned to the drawworks. Two generators will provide more than sufficient torque on the drawworks motor for the heaviest hook load but maximum hook speed will be reduced.

Thus, after making the electric setup connections, normal operation of the rig requires the driller to control the following devices: the motor master speed controllers; the drill-hoist selector switch; the rotary table spinout switch; drawworks jaw clutches; and the drawworks brake.

Test Results

Tests were taken with recording voltmeters and ammeters on Cote Blanche number 1 at various depths from 9,000 to about 11,000 feet.

Rotary Table

Tests made on the rotary table showed a wide variation in table torque. The minimum torque noted occurred at 9,800 feet and at 80 rpm and was 1,550 pound feet. The maximum torque was 6,400 pound feet at 75 rpm. These values compare with a rated motor torque of

6,900 pound feet when referred to the rotary table.

The test records showed that a torque of 13,400 pound feet was maintained for approximately seven minutes at standstill or at creep speed. This is 195 per cent of rated motor torque and was the highest sustained torque noted during the tests. Unfortunately the testers were so busy elsewhere that they failed to note just what the driller was trying to accomplish. In general, the torque on the rotary table at approximately 10,000 feet was 5,000 pound feet or less.

The rotary table motor provides permissible speeds of the rotary table from 0 to 340 rpm. Maximum speed observed during the test was 135 rpm. Normal drilling speeds varied from 75 to 135 rpm.

The maximum power requirement noted (140 horsepower) occurred when drilling at 135 rpm with 5,400 pound-feet torque on the rotary table.

Figure 8 plots table horsepower, table revolutions per minute, and depth of well versus elapsed drilling time for a typical test. The variation in power requirements can be observed from a depth of 9,570 feet to a depth of 9,810 feet and for a period of elapsed drilling time of 18 hours. It can be seen that the ratio of horsepower to table revolutions per minute varies considerably, but is less than one in all cases, except from time = 360 minutes to time = 450 minutes. Thus, the usual "rule-of-thumb" that about one horsepower per table revolutions per minute is required seems to be borne out.

Figure 8 indicates that the minimum power requirements for rotation (with light weight on the bit) are quite low. This would indicate that a large percentage of the power input to the rotary table is actually required to overcome the friction due to mud drag and due to friction between the drill stem and the periphery of the hole. For deeper wells it appears that the rotary table power requirements would not greatly exceed present requirements for comparable speeds as the total drill stem torque is primarily bit torque.

Figure 9 is a typical section of a strip chart of rotary table current.

The maximum torque is approximately 12,500 pound feet at time = 10 minutes on the chart. On the average, the torque varies from 1,800 pound feet to 5,600 pound feet. The time variation of torque is not evident from this chart because of the slow speed of the chart.

Figure 10(A) is a 6-inch-per-minute strip chart taken when drilling at a depth of 10,900 feet, showing rotary table current (that is, torque). The maximum and minimum torques are approximately 4,250 and 1,800 pound feet.

Figure 10(B) shows the variation in speed (calculated from voltage) from 80 to 100 rpm accompanying the torque variation shown in Figure 10(A).

Examination of Figures 10(A) and 10(B) shows that the torque oscillation slowly builds to a maximum sustained value. The period of the oscillation is approximately 4.8 seconds.

A rough calculation of the natural frequency of a system consisting of a torsional spring (the drill stem) and an oscillating mass (the rotary table motor) gave a calculated natural period of 2.2 seconds. The analysis did not include the effect of the rotary table inertia or the effect of the engine-generator set inertia. Taking account of these factors would increase substantially the calculated natural period. Since the calculated period and the measured period are of the same order of magnitude, it is reasonable to assume that these oscillations are natural frequency oscillations of the drill stem.

Figure 11 shows another strip chart taken at 6 inches per hour when drilling at a depth of 11,000 feet. There is no appreciable natural frequency oscillation of the drill stem indicated in this chart.

The rotary table torque resulting from variations in the drill bit pressure are shown clearly. Between time = 5 minutes and time = 40 minutes particularly, the increase in rotary table torque which occurs when the driller jogs the drawworks to payout line is evident. The torque varies from approximately 2,200 pound feet to 7,800 pound feet. In general, torque variations resulting from this cause are of a smaller magnitude than in this example.

During the rotary table test, the maximum rotary table speed observed was 135 rpm (59 per cent of rated motor speed). Reference to Figure 7 will show that the engine supplying the rotary table motor operated at base speed at all times, since the sustained torque does not exceed 6,400 pound feet (515 amperes).

Mud Pump Tests

Spot checks were taken of the mud pump power requirements during normal operation with one mud pump in operation. The depth of the well increased

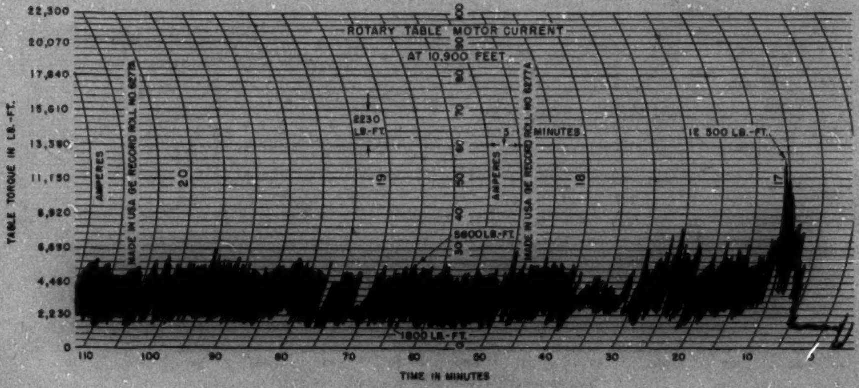

Figure 9. Section of rotary table motor current chart

Ordinate scale reads directly in pound feet of calculated table torque. Chart shows typical time variation of rotary table torque

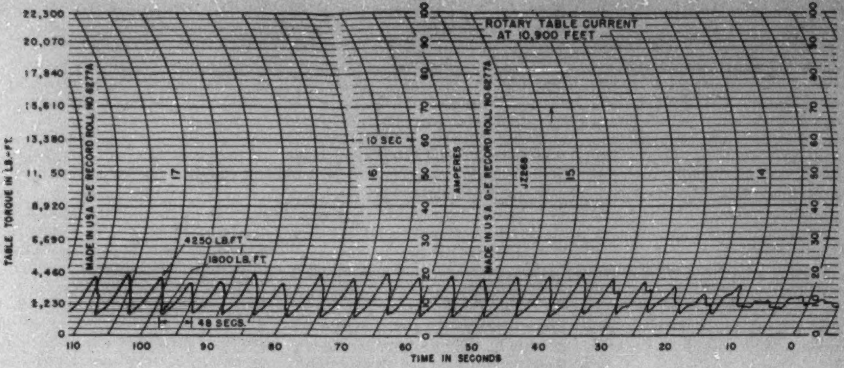

Figure 10(A). Section of rotary table motor current chart

Ordinate scale reads directly in pound feet of table torque. Chart shows periodic variation of motor torque resulting from drill stem oscillation

from 9,795 to 10,736 feet during the tests, while the pump pressure ranged from 1,000 to 1,150 pounds per square inch. The pump speed varied from 43 to 52 strokes per minute, (motor speed 87 to 105 per cent of rated) while the motor output varied from 272 to 448 horsepower. Reference again to Figure 7 will show that the engine supplying power to the mud pump operates at 65 per cent of rated revolutions per minute when supplying 272 horsepower (580 amperes, 87 per cent motor speed) and 82 per cent of rated revolutions per minute when supplying 448 horsepower (800 amperes, 105 per cent motor speed). Thus, the engines will operate from 65 to 82 per cent rated speed when driving the mud pumps.

Since these tests were taken, the mud pumps have been compounded (operated hydraulically in series), permitting maximum mud pressures of 2,400 pounds per square inch.

DRAWWORKS TESTS

A number of tests were taken on the drawworks motor to observe the driller's operation of the motor during the first half of a round trip (coming out of the hole).

Figure 12 shows the simultaneous speed and torque curves (calculated from voltage and current curves) of the drawworks motor plotted against time for hoisting one thribble with 118 thribbles of $5^1/_2$-inch drill pipe on the hook. The drawworks was in low-low gear (9.06/1) and there were eight lines to the traveling block. Two generators supplied power to the drawworks motor.

The driller's actions may be deduced from observation of the drawworks motor torque and speed curves. From 0 to 4 seconds, the driller was taking the slack out of the lines to make sure that he had a firm hold on the drill stem. At 5 seconds he turned the master switch to the full-speed position and the drawworks motor accelerated to maximum speed. At 20 seconds, the hook is traveling at its maximum speed which is determined by the maximum output power of the two engines. At 50 seconds, the end of the hoist is reached. At 54 seconds the driller started the drawworks motor, so that he could use the cathead to break the drill pipe joint. Between 57 and 64

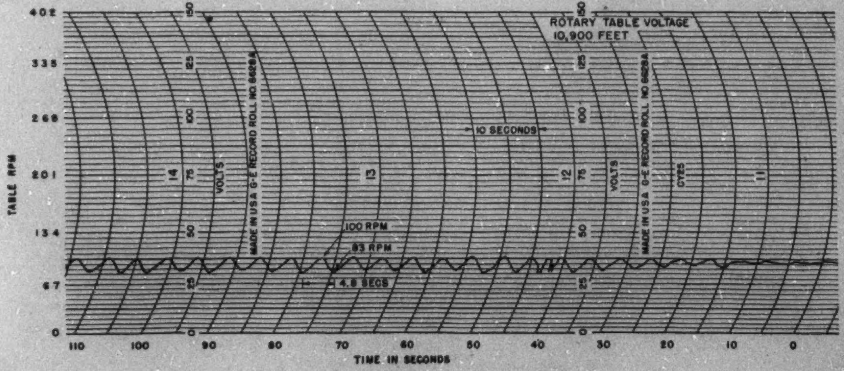

Figure 10(B). Section of rotary table motor voltage chart

Ordinate scale reads directly in calculated revolutions per minute of table motor. Chart shows periodic variation of motor speed seconds, the driller is unscrewing the thribble using the "spinout" arrangement on the rotary table. At 67 seconds the disconnected thribble is stacked at the side of the derrick. The hook is disconnected and dropped for the next hoist.

The engines accelerated to full speed at 5 seconds and remained at full speed until 45 seconds. At the beginning of the next cycle, the engines are again accelerated to top speed.

The next cycle would be almost identical with this one, except that the motor and hook maximum speeds would be slightly higher and the torque would be slightly lower. The time for the hoist would be reduced proportionately.

Figure 13 shows the operation of the drawworks motor during one complete hoisting operation. The tests were taken with a 10,691-foot hole, with eight lines to the block, with $5^1/_2$-inch drill pipe, and with two generators connected to the drawworks. For purposes of these curves one thribble is assumed to weigh 1,550 pounds net and the hook is assumed to weigh 20,000 pounds.

The curve shows the increase in motor speed as the load on the hook is reduced. Further calculations would show that the product of torque and revolutions per minute (power) as given in Figure 10 would not be constant as it should be if the possibilities of the system are utilized fully. The driller was not at all interested in making our test results beautifully consistent. As shown in Table II, the drawworks was operated with needlessly large gear ratios so that the motor speed was excessive. If the proper gear ratios had always been selected, the speed of hoisting could have been increased.

Table II

Gear Ratio	10 Lines: Minimum Weight in Pounds	10 Lines: Length of $5^1/_2$ Drill Stem in Feet	8 Lines: Minimum Weight in Pounds	8 Lines: Length of $5^1/_2$ Drill Stem in Feet
Three Generators				
Low-low	420,000	23,800	336,000	13,800
High-low	263,000	14,400	210,000	11,300
Low-high	163,000	8,500	130,000	6,500
High-high	0	0	0	0
Two Generators				
Low-low	280,000	15,400	224,000	12,100
High-low	175,000	9,200	140,000	7,100
Low-high	109,000	5,300	87,000	4,000
High-high	0	0	0	0
One Generator				
Low-low	140,000	7,100	112,000	5,500
High-low	88,000	4,000	70,500	3,000
Low-high	55,500	2,100	44,000	1,450
High-high	0	0	0	0

In Figure 14 the hook speed is plotted against the net weight of the drill stem using data from Figure 13. The figure shows that the operator shifted from low-low gear to high-low gear with 164,000 pounds net weight while Table II shows that the gears should have changed from low-low with 224,000 pounds net weight. The fact that the change in gear ratio gave no immediate increase in speed of the hook indicated that the driller could have shifted to high-low gear sooner with some benefit.

Figure 15 is based upon the same set of data as Figures 13 and 14 and shows the time of hoisting to remove a thribble plotted against the weight on the hook. The total cycle time, which includes the time between hoists, also is shown. The time between hoists varies quite widely and only those values which indicate that the crew is working constantly at a normal speed are used.

Figure 16 is based on test data and shows the amount of weight that can be lifted in any gear ratio and the proper gear ratio to use to take advantage of the constant horsepower characteristics of the system.

The horizontal broken lines enclosed by brackets show the upper and lower limits of drawworks motor current that should be used for best operation with three generators. The limits that should be used for one or two generators can be obtained by proper reduction of the limits shown for three generators. The top horizontal broken line shows the maximum current available from the three generators and indicates for any gear

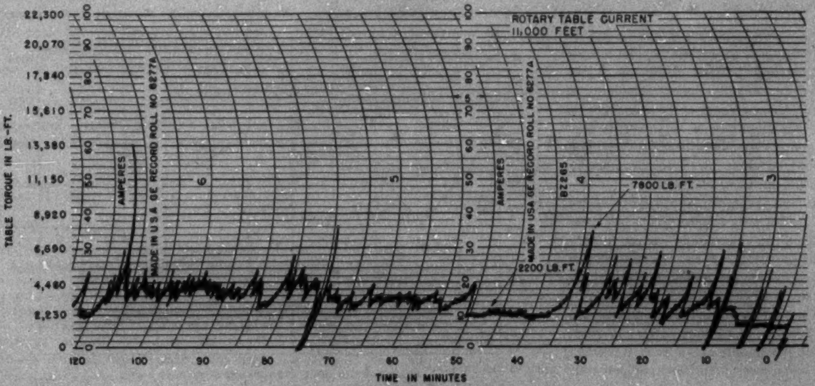

Figure 11. Section of rotary table motor current chart

Ordinate scale reads directly in terms of pound feet of calculated motor torque. Chart shows variation in table torque resulting from manual control of weight on drill bit ratio the amount of weight that may be lifted (no acceleration).

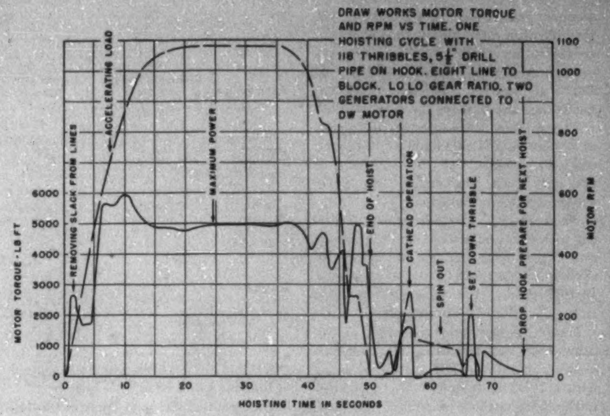

Figure 12. Typical drawworks motor torque and speed curves when "coming out of the hole"

Tests were taken while removing one "thribble" (90-foot section of drill stem)

The proper gear ratios to be used are shown in Table II.

If the values recommended here are checked against the weights at which the gears were shifted in Figure 13, the error becomes apparent.

The mechanical efficiency of the hoisting equipment from the motor shaft to the bottom of the hole was calculated to be approximately 70 per cent using the following definition of efficiency:

$$\text{Mechanical Efficiency} = \frac{W \times R}{N \times GR \times Tcalc}$$

where

W = total drill stem weight plus mud buoyancy factor + hook weight in pounds
R = drawworks drum radius in feet
N = number of lines to traveling block
GR = drawworks gear ratio
$Tcalc$ = calculated drawworks motor torque in pound feet necessary to lift weight W, without acceleration calculated from armature and field current

The losses included in the efficiency calculation are:

1. The drawworks chain drive and drum losses.
2. The line losses.
3. The crown block losses.
4. The traveling block losses.
5. The friction losses in the hole.

Discussion of Test Results

Rotary Table

As shown in Figure 8, the torque requirements of the rotary table for normal drilling will be one continuous horsepower per table revolution per minute or less. Although none of the tests taken on this rig show torque requirements substantially exceeding this value, provision should be made for higher torques for unusual operating conditions.

Since a properly designed electric drive will permit peak torques of 2 to $2^1/_2$ times normal, an electrically driven rotary table providing a normal rated torque of 1 horsepower per table revolution per minute is adequate.

The rig tested provided a normal rated table torque of 1.3 horsepower per revolution per minute and a peak torque of 3.4 horsepower per revolution per minute.

The oscillations shown in Figure 10(A) may occur with any type of rotary-table drive (electric, mechanical, or steam) although the natural period and magnitude may vary considerably. While this type of oscillation is known to exist in rotary tables driven by other types of drives, it can be measured and recorded most easily with the electric drive.

The variations in rotary table torque resulting from manual control of the weight on the drill bit are shown clearly in Figure 11. While it is recognized that the selection of the proper weight to be held on the bit is not an exact science, it is safe to say that either the weight corresponding to 7,800 pound feet torque was too high, or that the weight corresponding to 2,200 pound feet torque was too low for maximum drilling speed. This rig has a hydraulic drag device (not used during the tests) which simplifies greatly the problem of maintaining constant weight on the bit. The use of bit weight controlling equipment offers the following advantages:

1. The optimum weight on the bit may be held within close limits for a given strata resulting in the greatest drilling progress.

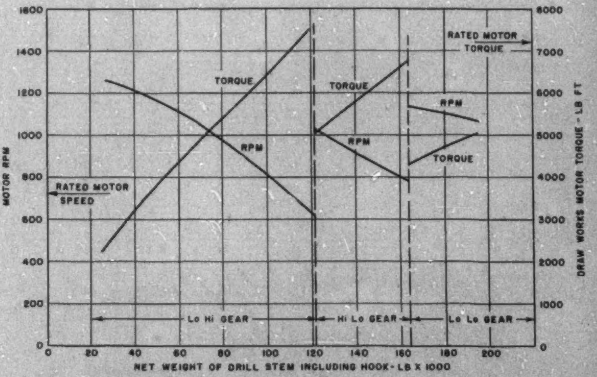

Figure 13. Motor torque and revolution per minute plotted against net weight of drill stem

Calculated from test data taken "coming out of the hole" from 10,691 feet with 8 lines to traveling block and using two engines

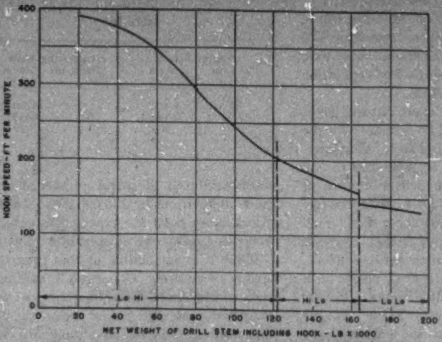

Figure 14. Calculated hook speed versus net weight of drill stem Data taken "coming out of the hole" from 10,691 feet with 8 lines to traveling block using two engines

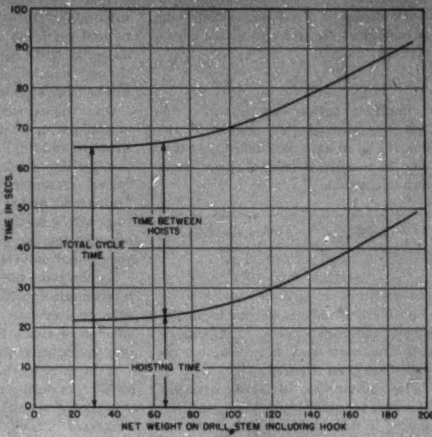

Figure 15 (right). Hoisting time to remove a "thribble" plotted against net weight of drill stem

2. The driller is relieved of the demanding and fatiguing duty of attempting to maintain proper bit loading manually.

Mud Pumps

Since the test data were taken the mud pumps have been operating compounded (hydraulically in series) by using a precharged air chamber as a surge tank between the two pumps. Operation has been satisfactory.

Drawworks

The test data indicated that 50 seconds was the average time between hoists (drawworks motor not rotating). An empirical equation expressing hoisting time as a function of net drill pipe weight and peak drawworks horsepower was set up. From these data an empirical equation relating the drawworks motor continuous horsepower rating, the drawworks motor peak horsepower and the maximum net weight to be hoisted was set up. The equation is

$$\frac{hp_c}{hp_p}=\sqrt[3]{\frac{hp_p+0.015W}{7.9hp_p+0.022W}}$$

where

hp_c = continuous horsepower rating of motor
hp_p = peak horsepower rating of motor
W = maximum net weight of drill stem to be hoisted in pounds

The preceding equation gives the continuous rating of the drawworks motor based upon heating considerations only. For reasonable values of hp_p and W, the ratio hp_p/hp_c will have a value of 1.6 to 1.8.

In order to calculate the amount of power required to hoist the drill stem, the following formula which assumes an efficiency of 65 per cent and a mud buoyancy factor of 0.85 may be used.

$$hp_p=\left(\frac{W_1}{25,000}+0.9\right)S$$

where

S = drill stem speed in feet per minute
hp_p = peak horsepower rating of motor
W_1 = total weight of drill stem in pounds (in air)

The 0.9 factor represents empty hook weight.

To the writers' knowledge, this rig operates with more power on the drawworks than any other rig now in existence. However the drawworks does not have more power than can be used effectively.

The power to be applied to the drawworks of a diesel electric rig is dependent primarily upon the selection of the other main drives. Engine-driven generators of proper size and number to provide power simultaneously to two mud pumps, one mud mixer, and the rotary table should be selected. The drawworks

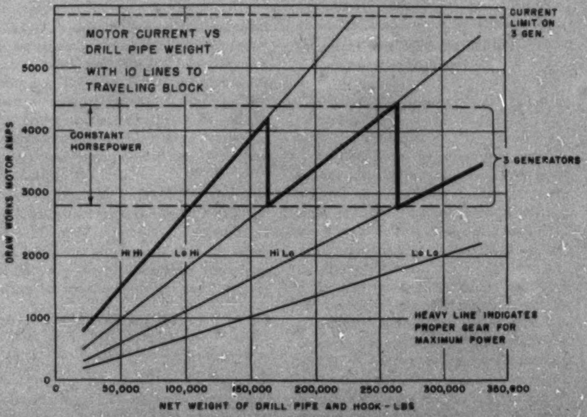

Figure 16. Curves calculated from test data indicating proper drawworks gear ratio to operate engine-generator sets on constant horsepower section of generator volt-ampere characteristic

motor should be of sufficient size to take advantage of the entire available engine capacity.

ENGINES

The diesel engines had been in operation approximately ten months at the time the latest data were taken. At that time the number of hours of operation on each engine was:

Engine	Hours, Operation
1	4,475
2	4,364
3	4,354

Insufficient time has elapsed to predict engine maintenance costs. The costs to date have been small as no major overhauls have been required.

Fuel consumption on this rig averages 25 barrels for a full day's operation. Assuming a delivered price of $0.07 per gallon, the fuel costs for a single day's operation is $74.

It is estimated that a heavy steam rig doing the same drilling duty would consume 1,000,000 to 2,500,000 cubic feet of natural gas in 24 hours. Based upon a charge of $0.13 per thousand cubic feet, the cost of fuel for a single day's operation will be from $130 to $325.

On a wildcat well where natural gas is unavailable, it would be necessary for the steam rig to burn liquid fuel. Consumption per day would be from 200 to 250 barrels. Assuming a delivered price of "Bunker C" fuel at $2 per barrel, the fuel costs will be $400 to $500 per day. Fuel consumption on heavy steam rigs has gone as high as 300 barrels per day ($600).

By analyzing the recording charts for a representative period of time, it is possible to calculate from Table III the amount of time that the engines have been operating at the various speeds.

If the three engines had been operating at 900 rpm during the total 13,193 hours of recorded operation, they would have completed 712,000,000 revolutions at top speed.

Actually, the electrohydraulic governor has required the engines to turn only 28,500,000 revolutions at top speed and has reduced the total number of required revolutions by 273,000,000. Low-maintenance costs are expected to result from this type of engine operation.

Table III

Engine Speed,		Operating Time	
Per Cent	Rpm	Per Cent	Hours
50	450	47	6200
50–85	450–765	49	6466
100	900	4	527

While it is impossible at this time to predict accurately the overall drilling costs of the large diesel electric rig as compared with the heavy steam rig, it appears that the cost advantage will be in favor of the diesel electric rig for production drilling when proper fuel charges are assigned.

Drilling a wildcat well where natural gas is unavailable will increase considerably the cost of operating the steam rig giving a substantially greater advantage in over-all drilling costs to the diesel electric rig.

No Discussion

The Vector Power Factor of Unbalanced Sinusoidal 3-Phase Circuits

J. F. LAMB
MEMBER AIEE

D. B. BRANDT
ASSOCIATE AIEE

WHEN the definitions of reactive power, vector power, and vector power factor,[1,2] of a polyphase circuit were established, the effects of unbalance were given considerable thought. Various suggestions[3,4,5] had been made to define "balance" or "unbalance" factors of different kinds in attempts to provide for the phenomena of power factor separately from those of unbalance. The development of the theory of symmetrical components led to the suggestion[4] of defining the power factor of an unbalanced polyphase load as being equal to the power factor of the positive sequence power input to the load.

During the time of this discussion, which was centered chiefly in the period from 1920 to 1935, many interesting facts regarding the effects of unbalance upon the power factor of a polyphase load were brought out. For example, it was well known that, with balanced line voltages. the vector power factor of a 3-wire 3-phase load became equal to the power factor of the positive sequence power input.

In some discussions, the authors confined their remarks to circuits having only current unbalance and assumed that line voltage unbalance could normally be neglected.

The reasons for many of the facts presented were often omitted, or, if included in the discussion, were usually of a specialized nature. The vast majority of the discussions were limited to the 3-wire 3-phase circuit.

The purpose of this paper is to develop expressions in which the part played by specific unbalance of current and voltage upon the magnitude of the vector power factor is clearly evident. The method of symmetrical components offers an approach by the use of voltage and current unbalance factors.

V. Genkin[6,7,8] has applied such unbalance factors to analyze the errors involved in the metering of reactive power and in investigating the "unbalance factor" of 3-phase, 3-wire loads. The unbalance factor considered by him was defined as the ratio of the pulsating component of 3-phase power to the vector volt amperes.

We are chiefly interested in the effect of unbalance upon the vector power factor, which quantity has been officially defined in the ASA Standards and is the basis for many power rates which include low power factor penalties. No official definition of power unbalance factor has as yet been incorporated into American standards.

Let us consider a 4-wire 3-phase star-connected load with the quantities of interest defined in Appendix I. All voltages and currents are assumed to be sinusoidal. We can at once write the vector expression for the volt-amperes[9,10] as

$$P+jQ=3E_1^*I_1+3E_2^*I_2+3E_0^*I_0=3\times(E_1I_1\cos\theta_1+E_2I_2\cos\theta_2+E_0I_0\cos\theta_0)+j3(E_1I_1\sin\theta_1+E_2I_2\sin\theta_2+E_0I_0\sin\theta_0) \qquad (1)$$

Expressing E_2, I_2, E_0, and I_0 in terms of the proper voltage and current unbalance factors multiplied by the corresponding positive sequence quantities, equation 1 then becomes

$$P+jQ=3E_1I_1(\cos\theta_1+K_{2v}K_{2i}\cos\theta_2+K_{0v}K_{0i}\cos\theta_0)+j3E_1I_1(\sin\theta_1+K_{2v}K_{2i}\sin\theta_2+K_{0v}K_{0i}\sin\theta_0)$$
$$=3E_1I_1(\cos\theta_1+K_2\cos\theta_2+K_0\cos\theta_0)+j3E_1I_1(\sin\theta_1+K_2\sin\theta_2+K_0\sin\theta_0) \qquad (2)$$

The vector power factor is then

$$\Lambda_v=\frac{P}{\sqrt{P^2+Q^2}} \qquad (3)$$
$$=\frac{\cos\theta_1+K_2\cos\theta_2+K_0\cos\theta_0}{[(\cos\theta_1+K_2\cos\theta_2+K_0\cos\theta_0)^2+(\sin\theta_1+K_2\sin\theta_2+K_0\sin\theta_0)^2]^{1/2}}$$

This expression can be reduced to

$$\Lambda_v=\frac{\cos\theta_1+K_2\cos\theta_2+K_0\cos\theta_0}{[1+K_2^2+K_0^2+2K_2\cos(\theta_1-\theta_2)+2K_0\cos(\theta_1-\theta_0)+2K_0K_2\cos(\theta_2-\theta_0)]^{1/2}} \qquad (4)$$

Equation 4 holds for a 3-phase, 4-wire circuit. For a 3-phase, 3-wire load, the zero sequence component of line current is zero, and hence K_0 is zero, and equation 4 reduces to

$$\Lambda_v=\frac{\cos\theta_1+K_2\cos\theta_2}{[1+K_2^2+2K_2\cos(\theta_1-\theta_2)]^{1/2}} \qquad (5)$$

An experimental check of equations 4 and 5 is given in Appendix II.

Practical Implications of the Derived Expressions

Referring to equation 4, the following points should be noted as applying to a 3-phase 4-wire load:

1. For both negative and zero-sequence unbalance, the effect of a given amount of unbalance in current is the same as that for an unbalance in voltage, since both K_2 and K_0 are the product of the corresponding voltage and current unbalance factors.

2. The vector power factor is dependent not only upon the magnitude of the unbalance factors but also upon the cosine of the angles θ_1, θ_2, θ_0, $\theta_1-\theta_2$, $\theta_1-\theta_0$, and $\theta_2-\theta_0$. However, the power factor is independent of the angles between the sequence voltages E_0, E_1, and E_2 once θ_0, θ_1, and θ_2 have been fixed. This means that the different sequence systems can be rotated independently of each other without affecting the vector power factor.

Paper 49-123, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE South West District meeting, Dallas, Tex., April 19–21, 1949. Manuscript submitted January 16, 1948; made available for printing February 24, 1949.

3. If the line currents are balanced, both K_2 and K_0 will be zero and the vector power factor reduces to $\cos\theta_1$, regardless of the voltage unbalance. Likewise if the phase voltages are balanced, the power factor will reduce to $\cos\theta_1$, regardless of the current unbalance.

4. If the line voltages are balanced, K_2 becomes zero. However K_0 is not necessarily zero, since a shift in the voltage neutral can occur even with no negative sequence component in the line voltage. If K_0 is not zero, but K_2 is zero, then the power factor will reduce to an expression similar to equation 5 but involving K_0 and θ_0 instead of K_2 and θ_2.

5. In the event that Z_a, Z_b, Z_c are equal, passive impedances, $\theta_1=\theta_2=\theta_0=$ impedance angle of the load, and the vector power factor reduces to $\cos\theta_1$ regardless of the voltage unbalance. In this case also

$$K_{2i}=K_{2v},\quad K_{0i}=K_{0v},$$

because the load impedance is the same for all sequence components. These relations do not hold necessarily when the load includes mutual inductances between phases or rotating machinery for which the impedances, although balanced between phases, are not the same for all sequence components.

The 3-wire 3-phase load to which equation 5 applies, is a special case of the more general 4-wire connection. It is apparent that any shift of the voltage neutral due to zero sequence voltages will have no effect upon the vector power factor of a 3-wire circuit since the K_0 terms are missing from equation 5.

For a 3-wire load, the vector power factor becomes equal to the positive sequence power factor if either the line voltages or the line currents are balanced, or if the load consists of balanced, static impedances. If the load consists of rotating machinery having an impedance to negative sequence currents different from that to positive sequence currents, an unbalance in voltage implies an unbalance in current and the complete expression in equation 5 must apply.

For most practical circuits, the unbalance factors K_0 and K_2 are small, since they are the products of current and voltage unbalance factors, each less than unity. Multiplication by $\cos\theta_0$ or $\cos\theta_2$ and so forth, further reduces the magnitudes of some of the terms involved. Hence, even for badly unbalanced circuits, the vector power factor may often be approximately equal to $\cos\theta_1$. This is evident from the numerical examples worked out in Appendix II. Only in test 5, Table II, does the vector power factor differ markedly from $\cos\theta_1$.

In this connection, another point should be noted. For high power factor loads, $\cos\theta_1$ will be close to unity, and the unbalance terms will be small in comparison. For low-power factor loads, $\cos\theta_1$ will be small, as for example test 5, Table II, and the unbalance terms will have a relatively greater importance in the determination of vector power factor. The fact that $\cos\theta_0$, $\cos\theta_2$, and so forth can be negative for many loads complicates the detailed analysis for this point.

In conclusion, it is evident that the relations developed in equations 4 and 5 make possible a clear conception of the different effects of various kinds of unbalance upon the vector power factor of a 3-phase load for sinusoidal applied voltages and currents.

Appendix I. Nomenclature

The nomenclature is based upon a star-connected 3-phase load with sinusoidal currents and voltages. Phase A is used as the reference phase for symmetrical component quantities.

I_a, I_b, I_c, I_n = currents in the corresponding line wires and neutral wire respectively
E_a, E_b, E_c = phase voltages to neutral
E_{AB}, E_{BC}, E_{CA} = line voltages
$\mathbf{Z}_a$, $\mathbf{Z}_b$, $\mathbf{Z}_c$ = complex phase impedances
$\mathbf{I}_1$ = complex positive sequence component of line current
$\mathbf{I}_2$ = complex negative sequence component of line current
$\mathbf{I}_0=\mathbf{I}_n/3$ = complex zero sequence component of line current
$\mathbf{E}_1$ = complex positive sequence component of phase voltage
$\mathbf{E}_2$ = complex negative sequence component of phase voltage
$\mathbf{E}$ = complex zero sequence component of phase voltage
$\mathbf{E}_1^*$, $\mathbf{E}_2^*$, $\mathbf{E}_0^*$ = complex conjugate values of the corresponding sequence voltages
I_1, I_2, I_0, E_1, E_2, E_0 = magnitudes of the corresponding complex quantities
P_a, P_b, P_c = active power in watts in the corresponding phases

Table II. Computed Quantities

Actual Voltage Drop to Neutral Across Phase A is Used as the Reference Vector

Quantity	Test 1	2	3	4	5

$\cos\theta_1$	0.995	0.998	0.986	0.993	0.691
Power Factor*	0.994	1.00	0.957	0.998	0.462
Power Factor**	0.993	1.00	0.950	1.00	0.457

* = power factor computed from equation 4.

** = power factor computed from the sums of wattmeter and varmeter readings for all three phases.

Q_a, Q_b, Q_c = reactive power in vars in the corresponding phases

$P = P_a + P_b + P_c$ = watts total active power in the 3-phase load

$Q = Q_a + Q_b + Q_c$ = total reactive power in vars in the 3-phase load (algebraic summation)

θ_1 = time phase angle between E_1 and I_1

θ_2 = time phase angle between E_2 and I_2

θ_0 = time phase angle between E_0 and I_0

$K_{2I} = I_2/I_1$ and $K_{0I} = I_0/I_1$ = respective negative sequence and zero sequence current unbalance factors

$K_{2E} = E_2/E_1$ and $K_{0E} = E_0/E_1$ = respective negative sequence and zero sequence voltage unbalance factors

$K_2 = K_{2I} \times K_{2E}$ = negative sequence unbalance factor

$K_0 = K_{0I} \times K_{0E}$ = zero sequence unbalance factor

Λ_v = lambda, the vector power factor as defined in reference 1

Appendix II. Experimental Check

An experimental check of equations 4 and 5 was made by applying unbalanced voltages to several unbalanced 3-phase loads. The loads consisted of three impedances connected in star to form either a 3-wire or a 4-wire system. The test readings for five different examples are given in Table I. The results computed to within slide rule accuracy from the data of Table I are shown in Table II. No attempt was made to correct the test readings in Table I for ratio or phase angle errors involved in the use of current transformers. Potential circuit measurements were made directly without using potential transformers. The negative varmeter readings in Table I indicate inductive reactive power.

The agreement of the figures in the last two rows of Table II indicates that the experimental measurements checked the values computed using equations 4 and 5 very closely.

The Negative-Sequence Reactances of an Ideal Synchronous Machine

WILLIAM C. DUESTERHOEFT
ASSOCIATE AIEE

THE METHOD of symmetrical components is at present used widely in determining fundamental-frequency components of current and voltage in unbalanced 3-phase power systems. To apply this method, the sequence impedances of the various circuits which make up the system are required. As synchronous machines are present in all systems, determination of their reactances is of prime importance.

Before a specified reactance can be determined it must be definitely defined and, preferably, a method of testing for this reactance given. This is the general procedure followed by the Institute in standardizing electrical terms.[1] Because of saturation in synchronous machines, it may be necessary to specify the degree of saturation at which the test is to be made. This may be done by recognizing two values of reactance, one determined at rated current and the other at rated voltage. The two values should be identical if saturation is negligible.

As progress is made in the analysis of synchronous machine performance, it becomes necessary to specify the various reactances encountered with increasing accuracy. A paper discussing inherent errors in the prescribed AIEE method of determining direct-axis transient and subtransient reactances (x_d' and x_d''), by test, has been presented.[2]

The purpose of this paper is to show that there are many values of the negative-sequence reactance of a synchronous machine, as it is now defined. If only the machine is considered, without load and with negligible saturation, there are as many values of this reactance as there are types of unbalanced short-circuits; and none of these values is independent of the connected circuit. The number of negative-sequence reactances can be reduced readily to one by modification of the present definition. If so modified, the specified reactance may not be the proper one for use under all conditions where fundamental-frequency components of current and voltage are to be calculated by the method of symmetrical components, as conventionally applied. It would, however, have the advantage of being definite, and could be modified as required.

Definition of Negative-Sequence Reactance

In the American Standard Definition of Electrical Terms,[1] the following definition of negative-sequence reactance (x_2) is given under 10.35.170:

> "NEGATIVE-SEQUENCE REACTANCE (x_2)
>
> "The negative-sequence reactance is the ratio of the fundamental component of reactive armature voltage, due to the fundamental negative-sequence component of armature current, to this component of armature current at rated frequency.
>
> "The rated current value of negative-sequence reactance is the value obtained from a test with a current equal to rated armature current.
>
> "The rated voltage value of negative-sequence reactance is the value obtained from a line-to-line short-circuit test at two terminals of the machine at no-load and rated speed, and at rated armature voltage."

This definition of x_2 is somewhat ambiguous. It has been interpreted as implying that the only currents present are those of fundamental frequency. However, as this is not so stated, it is here understood to mean that there is no restriction on the harmonic currents and voltages which may be present.

If the first interpretation is accepted, there is only one definition of the negative-sequence reactance of an ideal synchronous machine. By this interpretation (see Appendix II, equation 22),

$$x_2=(^1/_2)(x_d''+x_q'') \tag{1}$$

where x_d'' and x_q'' are direct- and quadrature-axis subtransient reactances, respectively. Rated current value of x_2, as defined, is consistent with the first interpretation if "rated armature current" is understood to mean "fundamental-frequency negative-sequence current of rated magnitude." (Rated armature current usually signifies balanced currents of positive-sequence phase order.)

The rated voltage value of x_2, as defined, is only one of the many values of x_2 which are influenced by the presence of odd harmonic components of current. It is a special case, consistent with the second interpretation of the definition. This value of x_2, applicable for a line-to-line short circuit at the terminals of the machine at "no-load and rated speed, and at rated armature voltage," has already been given.[3,4] (See also Appendix III, equation 31). It is

$$x_2=\sqrt{x_d''x_q''} \tag{2}$$

where x_d'' and x_q'' are direct- and quadrature-axis subtransient reactances, respectively. A rated voltage value of x_2, consistent with the first interpretation of the definition, could be obtained from a test with impressed negative-sequence currents of fundamental frequency such as to produce a negative-sequence reactive armature voltage, equal in magnitude to rated armature voltage. In this test, as in the corresponding test for the rated current value of x_2, negative-sequence currents can be applied through high

---

Paper 49-127, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE South West District meeting, April 19–21, 1949, Dallas, Tex. Manuscript submitted February 2, 1949; made available for printing March 10, 1949.

WILLIAM C. DUESTERHOEFT is with the Department of Electrical Engineering, the University of Texas, Austin, Tex.

The author gratefully acknowledges the helpful suggestions of Miss Edith Clarke in the preparation of this paper.

reactances to third-harmonic currents, so that third-harmonic voltages resulting from negative-sequence currents will exist at the machine terminals but will produce negligible currents.

Effect of Harmonics on Negative-Sequence Reactance

It has long been known that negative-sequence currents of fundamental frequency, flowing in synchronous machines in which the direct- and quadrature-axis reactances (x_d'' and x_q'') are unequal, produce positive-sequence third-harmonic voltages. When the system is unbalanced and the third-harmonic impedance is finite, positive-sequence third-harmonic voltage will cause both positive- and negative-sequence third-harmonic currents to flow and, in the case of ground faults in a grounded system, zero-sequence third-harmonic currents also. Negative-sequence third-harmonic currents produce positive-sequence fifth-harmonic voltages in the synchronous machine, and positive-sequence third-harmonic currents produce negative-sequence voltages of fundamental frequency. Negative-sequence currents of any odd harmonic order produce positive-sequence voltages of the next higher odd harmonic order; and positive-sequence voltages of any odd harmonic order above the fundamental produce negative-sequence voltages of the next lower odd harmonic order.[5] If the system is unbalanced and all impedances are finite, each harmonic voltage will produce positive- , negative- , and possibly zero-sequence currents, of the same harmonic order.

It can be concluded, therefore, that all odd-order harmonic currents will be present.

From the equations derived in the appendices and elsewhere,[3,4,5] it is evident that fundamental-frequency components of negative-sequence voltage or current, or both, are affected by the presence of odd harmonic currents in machines in which $x_d'' \neq x_q''$. Negative-sequence reactance, as now defined, will therefore be affected by their presence. It is only where negative-sequence reactance is defined in terms of applied currents of fundamental frequency (which implies that harmonic currents are prevented from flowing) that negative-sequence reactance has one definite value.

Negative-Sequence Reactance with Ground Faults

The negative-sequence reactance, as now defined, of an unloaded synchronous machine with a ground fault at its terminals will be influenced by the zero-sequence reactance x_0 viewed from the fault.

For a line-to-ground fault, from Appendix III, equation 37, x_2 by definition is

$$x_2=\sqrt{\left(x_d''+\frac{x_0}{2}\right)\left(x_q''+\frac{x_0}{2}\right)}-\frac{x_0}{2} \qquad (3)$$

For a double line-to-ground fault, from Appendix III, equation 50, x_2 is

$$x_2=\frac{2x_0\sqrt{x_d''x_q''}}{\sqrt{(x_d''+2x_0)(x_q''+2x_0)}-\sqrt{x_d''x_q''}} \qquad (4)$$

Negative-Sequence Reactance in Terms of Applied Negative Sequence Voltage

The following definition of negative-sequence reactance, analogous to that of the rated voltage value of a positive-sequence reactance, has been suggested:[4]

> Negative-sequence reactance is the ratio of applied negative-sequence voltage to the fundamental component of reactive negative-sequence current which it produces.

With balanced negative-sequence voltages applied to the machine terminals, from Appendix IV, equation 60, x_2 by this definition is

$$x_2=(2x_d''x_q'')/(x_d''+x_q'') \qquad (5)$$

As balanced voltages are applied, the positive-sequence third-harmonic voltages which are produced by the flow of negative-sequence currents are short circuited by the applied voltages and produce third-harmonic positive-sequence currents. However, since the system is balanced, no negative-sequence third-harmonic currents will flow. Third-harmonic positive-sequence currents, as previously explained, produce negative-sequence voltage of fundamental frequency which, in turn, produces negative-sequence currents. The resultant negative-sequence current is affected by the presence of the third-harmonic currents, while the applied negative-sequence voltage is unaffected.

The value of x_2 given by equation 5 is applicable only when the voltages at the machine terminals are balanced voltages of negative-sequence phase order.

Relative Values of x_2 Calculated from Equations 1–5

The greatest variation in the values of x_2 occurs in the case of a salient-pole machine without an amortisseur winding. For example, the values of x_2 calculated for a machine with $x_d''=0.30$, $x_q''=0.70$, $x_0=0.10$ are 0.500, 0.458, 0.451, 0.432, and 0.420 when computed from equations 1–5, respectively. A machine with amortisseur windings such that $x_d''=x_q''$ would have $x_2=x_d''=x_q''$.

Conclusions

1. Negative-sequence reactance x_2 determined in accordance with its present definition is a reactance which depends upon system conditions.

2. The rated current and rated voltage values of x_2, as now given, are special cases. These two values of x_2 are not the same in an unloaded machine of negligible saturation.

3. It is suggested that the definition be revised and x_2 be so defined that it has a definite value, affected only by saturation. This can be done by adding "with the effects of harmonics neglected" to the definition. The rated current value will then be consistent with the definition if "with a current equal to rated armature current" be replaced by "with fundamental negative-sequence current equal in magnitude to rated armature current." It is further suggested that the rated voltage value be changed to agree with the revised definition.

4. If the foregoing suggestions are adopted, x_2 will have a definite value: $x_2=(1/2)(x_d''+x_q'')$. Then, if harmonics are known to be appreciable, their effects can be considered separately and superposed.[5]

5. For unbalanced short circuits at the terminals of an unloaded machine, the values of x_2 given by equations 2, 3, and 4, which include the effects of harmonics, are applicable.

Appendix I

The method used to derive the equations of this paper utilizes Park's equations for the ideal synchronous machine,[6,7] expressed in terms of $\alpha\beta 0$ components.[8] These equations are used to determine expressions for the components of current which include the effects of all harmonics.

The fundamental-frequency components of these currents are found by the method of harmonic analysis.

On the assumption of constant unit rotor speed, Park's equations[7] for the ideal synchronous machine[6] during the first instant after fault, expressed in per unit of machine base quantities, become

$$\begin{aligned} e_d&=I_f-(px_d''+r)i_d+x_q''i_q\\ e_q&=-x_d''i_d-(px_q''+r)i_q\\ e_0&=-(px_0+r)i_0 \end{aligned} \qquad (6)$$

where I_f is the field current in per unit of that field current which produces unit armature voltage at no-load and rated frequency on the air-gap line. Subscripts d and q refer to direct and quadrature axes respectively; e indicates voltage and i current.

In terms of $\alpha\beta 0$ components of current and voltage, equations 6 become[8]

$$e_\alpha=-I_f\sin\theta-p(x+y\cos 2\theta)i_\alpha-\\ py\sin 2\theta i_\beta-ri_\alpha$$

$$e_\beta = I_f \cos\theta - py \sin 2\theta i_\alpha - p(x - y\cos 2\theta) i_\beta - r i_\beta \qquad (7)$$

$$e_0 = -(px_0 + r) i_0$$

where

$$\left.\begin{aligned} x &= \tfrac{1}{2}(x_d'' + x_q'') \\ y &= \tfrac{1}{2}(x_d'' - x_q'') \\ i_\alpha &= i_d \cos\theta - i_q \sin\theta \end{aligned}\right\} \qquad (8)$$

$$\left.\begin{aligned} i_\beta &= i_d \sin\theta + i_q \cos\theta \\ e_\alpha &= e_d \cos\theta - e_q \sin\theta \\ e_\beta &= e_d \sin\theta + e_q \cos\theta \end{aligned}\right\} \qquad (9)$$

The α, β, and 0 components of current i_α, i_β, and i_0, are defined in terms of the armature phase currents i_a, i_b, and i_c of phase order *abc* by the equations[4]

$$i_\alpha = \frac{2}{3}\left(i_a - \frac{i_b + i_c}{2}\right)$$

$$i_\beta = \frac{1}{\sqrt{3}}(i_b - i_c) \qquad (10)$$

$$i_0 = \frac{1}{3}(i_a + i_b + i_c)$$

The α component of current, i_α, is the component of armature current which produces a field in the axis of phase *a*; i_β is the component of armature current which produces a field in the common axis of phases *b* and *c* electrically perpendicular to the axis of phase *a*. Vectors representing sinusoidal i_α and i_β in the complex plane can be given in terms of the vectors representing positive- and negative-sequence currents. These vector equations[5] are

$$\left.\begin{aligned} \boldsymbol{I}_\alpha &= \boldsymbol{I}_{a1} + \boldsymbol{I}_{a2} \\ \boldsymbol{I}_\beta &= -j(\boldsymbol{I}_{a1} - \boldsymbol{I}_{a2}) \end{aligned}\right\} \qquad (11)$$

and

$$\left.\begin{aligned} \boldsymbol{I}_{a1} &= (\boldsymbol{I}_\alpha + j\boldsymbol{I}_\beta)/2 \\ \boldsymbol{I}_{a2} &= (\boldsymbol{I}_\alpha - j\boldsymbol{I}_\beta)/2 \end{aligned}\right\} \qquad (12)$$

The $\alpha\beta0$ components of voltage are related to the armature voltages and to symmetrical components of voltage by equations similar to 10–12 if *i* and *I* are replaced by *e* and ***E***, respectively, in these equations.

Armature resistances are usually small relative to reactances, and their omission does not affect appreciably the magnitudes or phases of the currents or voltages determined hereby solutions of equations 7. Decrement factors need not be considered as negative-sequence reactance is always a subtransient value. Equations 7 will be reduced on the assumption of negligible resistance to equations 13.

$$e_\alpha = -I_f \sin\theta - p(x + y\cos 2\theta) i_\alpha - py \sin 2\theta i_\beta$$

$$e_\beta = I_f \cos\theta - py \sin 2\theta i_\alpha - p(x - y\cos 2\theta) i_\beta \qquad (13)$$

$$e_0 = -px_0 i_0$$

Appendix II. Negative-Sequence Reactance to Applied Negative-Sequence Currents

If balanced fundamental negative-sequence currents are caused to flow in an unloaded machine, rotating at synchronous speed with the field winding short circuited but unexcited, $i_{a1} = 0$ and i_{a2} may be written

$$i_{a2} = I_2 \cos\theta \qquad (14)$$

Then, from equation 11

$$\left.\begin{aligned} i_\alpha &= I_2 \cos\theta \\ i_\beta &= -I_2 \sin\theta \end{aligned}\right\} \qquad (15)$$

When equations 15 are substituted in equations 13, the resultant α and β voltages at the machine terminals are

$$e_\alpha = -pI_2[x\cos\theta + y(\cos 2\theta \cos\theta - \sin 2\theta \sin\theta)] \qquad (16)$$

$$e_\beta = -pI_2[-x\sin\theta + y(\sin 2\theta \cos\theta + \cos 2\theta \sin\theta)] \qquad (17)$$

Since

$$\cos 2\theta \cos\theta - \sin 2\theta \sin\theta = \cos 3\theta$$

$$\sin 2\theta \cos\theta + \cos 2\theta \sin\theta = \sin 3\theta$$

Equations 16 and 17 can be simplified and differentiated to give

$$e_\alpha = 3yI_2 \sin 3\theta + xI_2 \sin\theta \qquad (18)$$

$$e_\beta = xI_2 \cos\theta - 3yI_2 \cos 3\theta \qquad (19)$$

If equations 18 and 19 are substituted in the voltage equations similar to equations 12, the resultant positive- and negative-sequence components of voltage, e_{a1} and e_{a2}, are found to be

$$e_{a1} = 3yI_2 \sin 3\theta \qquad (20)$$

$$e_{a2} = xI_2 \sin\theta \qquad (21)$$

The above development shows that fundamental negative-sequence current produces third-harmonic positive-sequence voltage and fundamental negative-sequence voltage. If the AIEE definition of negative-sequence reactance is taken to mean the ratio of the reactive fundamental negative-sequence voltage, produced by applied fundamental negative-sequence current, to that current, then

$$x_2 = \frac{1}{2}(x_d'' + x_q'') \qquad (22)$$

Appendix III. Negative-Sequence Reactances With an Unsymmetrical Short Circuit at the Terminals of the Ideal Synchronous Machine

An unloaded machine, operating at rated voltage and constant speed, will be assumed.

Line-to-Line Short Circuit

For a fault between phases *b* and *c*, conditions are $i_a = 0$, $i_b = -i_c$, and $e_b = e_c$. From equations 10

$$i_\alpha = i_0 = 0; \quad e_\beta = 0 \qquad (23)$$

If equation 23 is substituted in equation 13 and the resulting equation integrated, there results

$$i_\beta = \frac{I_f \sin\theta}{x - y\cos 2\theta} \qquad (24)$$

The integration constant is neglected since only the fundamental current is of interest, and the integration constant represents trapped flux which produces d-c and even harmonic currents. Equation 24 can be represented by a Fourier series of which the fundamental component $i_{\beta 1}$ is

$$i_{\beta 1} = \frac{2I_f \sin\theta}{(x + y) + \sqrt{x^2 - y^2}}$$

From equations 8

$$i_{\beta 1} = \frac{2I_f \sin\theta}{x_d'' + \sqrt{x_d'' x_q''}} \qquad (25)$$

The value of $i_{\beta 1}$ given by equation 25 is consistent with the value of i_b given by Doherty and Nickle.[8]

The symmetrical components of current, i_{a1} and i_{a2}, from equations 25 and 12 with $i_\alpha = 0$, are

$$i_{a1} = -i_{a2} = \frac{I_f \cos\theta}{x_d'' + \sqrt{x_d'' x_q''}} \qquad (26)$$

By the method of symmetrical components as conventionally applied, with resistance neglected

$$\boldsymbol{I}_{a1} = -\boldsymbol{I}_{a2} = \frac{\boldsymbol{E}_{a1}}{j(x_1 + x_2)} \qquad (27)$$

where $\boldsymbol{E}_{a1}$ is the vector representing the positive-sequence voltage at the machine terminals on open circuit. Its instantaneous value e_{a1}, from equations 12 and 13, is

$$e_{a1} = -I_f \sin\theta \qquad (28)$$

Therefore, instantaneous i_{a1} and i_{a2} are

$$i_{a1} = -i_{a2} = \frac{I_f \cos\theta}{x_1 + x_2} \qquad (29)$$

As the machine is operating at no-load and constant speed, with resistance neglected, fundamental positive-sequence currents appear in the direct-axis. Therefore

$$x_1 = x_d'' \qquad (30)$$

From equations 26, 29, and 30, it follows that

$$x_2 = x\sqrt{x_d'' x_q''} \qquad (31)$$

Line-to-Ground Short Circuit

The conditions are $i_b = i_c = 0$ and $e_a = 0$. From equations 10

$$i_\beta = 0; \quad i_\alpha = 2i_0; \quad e_\alpha = -e_0 \qquad (32)$$

If equations 32 are substituted in equations 13 and the resulting equations simplified and integrated to obtain a solution for i_α, with the integration constant neglected, there results

$$i_\alpha = \frac{I_f \cos\theta}{x + \dfrac{x_0}{2} + y\cos 2\theta} \qquad (33)$$

The above expression can be represented by a Fourier series of which the fundamental component i_{a1} is

$$i_{a1} = \frac{2I_f \cos\theta}{x_d'' + \dfrac{x_0}{2} + \sqrt{\left(x_d'' + \dfrac{x_0}{2}\right)\left(x_q'' + \dfrac{x_0}{2}\right)}} \qquad (34)$$

The fundamental-frequency symmetrical components of current, i_{a1}, i_{a2}, and i_0, from equations 12, 32, and 34, are

$$i_{a1}=i_{a2}=i_0=\frac{I_f\cos\theta}{x_d''+\frac{x_0}{2}+\sqrt{\left(x_d''+\frac{x_0}{2}\right)\left(x_q''+\frac{x_0}{2}\right)}} \quad (35)$$

In the symmetrical component method

$$I_{a1}=I_{a2}=I_0=\frac{E_{a1}}{j(x_1+x_0+x_2)}$$

and, since E_{a1} is the vector representing the voltage given by equation 28

$$i_{a1}=i_{a2}=i_0=\frac{I_f\cos\theta}{x_1+x_0+x_2} \quad (36)$$

If equation 30 and the discussion preceding it are considered, x_2 from equations 35 and 36 is

$$x_2=\sqrt{\left(x_d''+\frac{x_0}{2}\right)\left(x_q''+\frac{x_0}{2}\right)}-\frac{x_0}{2} \quad (37)$$

Double Line-to-Ground Short Circuit

With phases b and c grounded, $i_a=0$ and $e_b=e_c=0$. From equations 10

$$e_\beta=0;\ e_\alpha=2e_0;\ i_\alpha=-i_0 \quad (38)$$

If equations 38 is substituted in equations 13, these equations can be reduced to

$$p(x+2x_0+y\cos 2\theta)i_\alpha+py\sin 2\theta i_\beta=-I_f\sin\theta$$

$$py\sin 2\theta i_\alpha+p(x-y\cos 2\theta)i_\beta=I_f\cos\theta$$

The above equations can be integrated and, if the integration constant is neglected, become

$$(x+2x_0+y\cos 2\theta)i_\alpha+y\sin 2\theta i_\beta=I_f\cos\theta \quad (39)$$

$$y\sin 2\theta i_\alpha+(x-y\cos 2\theta)i_\beta=I_f\sin\theta \quad (40)$$

By simultaneous solution of equations 39 and 40

$$i_\alpha=\frac{(x-y)I_f\cos\theta}{x^2-y^2+2x_0x-2x_0y\cos 2\theta} \quad (41)$$

$$i_\beta=\frac{(x-y+2x_0)I_f\sin\theta}{x^2-y^2+2x_0x-2x_0y\cos 2\theta} \quad (42)$$

The above expressions for i_α and i_β can be represented by Fourier series of which the fundamental components $i_{\alpha1}$ and $i_{\beta1}$ are

$$i_{\alpha1}=\frac{2x_q''I_f\cos\theta}{x_q''(x_d''+2x_0)+\sqrt{x_d''x_q''(x_d''+2x_0)\times(xq''+2x_0)}} \quad (43)$$

$$i_{\beta1}=\frac{2(x_q''+2x_0)I_f\sin\theta}{x_d''(x_q''+2x_0)+\sqrt{x_d''x_q''(x_d''+2x_0)\times(x_q''+2x_0)}} \quad (44)$$

By the method of symmetrical components, the fundamental positive- and negative-sequence components of current I_{a1} and I_{a2} are

$$I_{a1}=\frac{E_{a1}}{j[x_1+x_0x_2/(x_0+x_2)]}=\frac{E_{a1}(x_0+x_2)}{j(x_1x_0+x_1x_2+x_0x_2)} \quad (45)$$

$$I_{a2}=\frac{-I_{a1}x_0}{(x_0+x_2)}=\frac{-E_{a1}x_0}{j(x_1x_0+x_1x_2+x_0x_2)} \quad (46)$$

The vectors representing $i_{\alpha1}$ and $i_{\beta1}$, determined by substitution of equations 45 and 46 in 11, are

$$I_{\alpha1}=(-jx_2E_{a1})/(x_1x_0+x_1x_2+x_0x_2) \quad (47)$$

$$I_{\beta1}=-E_{a1}(2x_0+x_2)/(x_1x_0+x_1x_2+x_0x_2) \quad (48)$$

Equations 43, 44, 47, and 48 give two expressions for the ratio of $I_{\alpha1}$ to $I_{\beta1}$. If these two ratios are equated

$$\frac{x_2+2x_0}{x_2}=\frac{[x_q''+2x_0][x_q''(x_d''+2x_0)+\sqrt{x_d''x_q''(x_d''+2x_0)(x_q''+2x_0)}]}{[x_q''][x_d''(x_q''+2x_0)+\sqrt{x_d''x_q''(x_d''+2x_0)(x_q''+2x_0)}]}$$

From the above expression, it is shown that

$$\frac{x_2+2x_0}{x_2}=\frac{\sqrt{(x_d''+2x_0)(x_q''+2x_0)}}{\sqrt{x_d''x_q''}} \quad (49)$$

and

$$x_2=\frac{2x_0\sqrt{x_d''x_q''}}{\sqrt{(x_d''+2x_0)(x_q''+2x_0)}-\sqrt{x_d''x_q''}} \quad (50)$$

Appendix IV. Negative-Sequence Reactance to Applied Negative-Sequence Voltage

If fundamental negative-sequence voltage is applied to a machine, rotating at synchronous speed with the field winding short circuited but unexcited, $e_{a1}=0$ and e_{a2} may be written

$$e_{a2}=E_2\cos\theta \quad (51)$$

From voltage equations similar to equation 11

$$e_\alpha=E_2\cos\theta \quad (52)$$

$$e_\beta=-E_2\sin\theta \quad (53)$$

If equations 52 and 53 are substituted in equations 13

$$p(x+y\cos 2\theta)i_\alpha+py\sin 2\theta i_\beta=-E_2\cos\theta \quad (54)$$

$$py\sin 2\theta i_\alpha+p(x-y\cos 2\theta)i_\beta=E_2\sin\theta \quad (55)$$

If equations 54 and 55 are integrated, the solution for i_α and i_β can be shown to be

$$i_\alpha=\frac{E_2(-x\sin\theta+y\sin 3\theta)}{x^2-y^2} \quad (56)$$

$$i_\beta=\frac{E_2(-x\cos\theta-y\cos 3\theta)}{x^2-y^2} \quad (57)$$

Substitution of equations 56 and 57 in equation 12 gives the positive- and negative-sequence components of current, i_{a1} and i_{a2}.

$$i_{a1}=\frac{yE_2\sin 3\theta}{x^2-y^2} \quad (58)$$

$$i_{a2}=\frac{-xE_2\sin\theta}{x^2-y^2} \quad (59)$$

The above development shows that if negative-sequence voltage is applied to the machine, third-harmonic positive-sequence and fundamental negative-sequence currents are produced. If negative-sequence reactance is taken as the ratio of applied fundamental negative-sequence voltage to the reactive fundamental negative-sequence current it produces

$$x_2=\frac{x^2-y^2}{x}=\frac{2x_d''x_q''}{x_d''+x_q''} \quad (60)$$

The above equation is given by Park and Robertson.[4] The development given here in terms of α and β components, however, is different.

Discussion

W. A. Lewis (Illinois Institute of Technology, Chicago, Ill.): The paper by Mr. Duesterhoeft is, I believe, the first to publish the value of the negative-sequence reactance of a synchronous machine which is applicable during a double-line-to-neutral short circuit. The previous discussion of a double line-to-neutral fault by Smith and Weygandt[1] develops expressions for the short-circuit currents but does not give a specific value of the negative-sequence reactance.

By extending that analysis, I have derived the value for it, which agrees with equation 4 of the present paper.

The value for a single line-to-neutral fault has been published previously.[2] With the addition of the value for the double line-to-neutral case, there are now five significant values of negative-sequence reactance, as follows

$$X_2=\frac{X_d''+X_q''}{2}$$

$$X_{2(LN)}=\sqrt{\left(X_d''+\frac{X_0}{2}\right)\left(X_q''+\frac{X_0}{2}\right)}-\frac{X_0}{2}$$

$$X_{2(LL)}=\sqrt{X_d''X_q''}$$

$$X_{2(2LN)}=\frac{2X_0\sqrt{X_d''X_q''}}{\sqrt{(X_d''+2X_0)(X_q''+2X_0)}-\sqrt{X_d''X_q''}}=\left[\frac{X_d''X_q''+\sqrt{X_d''X_q''(X_d''+2X_0)(X_q''+2X_0)}}{X_d''+X_q''+2X_0}\right]$$

$$X_{2V}=\frac{2X_d''X_q''}{X_d''+X_q''}$$

In the listing given here the five values have been arranged in descending order. The first value, denoted by X_2, for sinusoidal negative-sequence current applied, is the largest. The value for a single line-to-neutral fault, $X_{2(LN)}$, lies between the first value and the value for a line-to-line fault, $X_{2(LL)}$, and depends upon X_0. If X_0 is zero, the value for a line-to-neutral fault becomes the same as that for a line-to-line fault, and if X_0 is infinite, it can be shown, by expanding $X_{2(LN)}$ by the binomial expansion, that $X_{2(LN)}$ approaches X_2 as a limit. Similarly, $X_{2(2LN)}$, the value applicable for a double line-to-neutral fault, varies from $X_{2(LL)}$ to X_{2V}, the value applicable when sinusoidal negative-sequence voltage is applied. If X_0 is zero, $X_{2(2LN)}$ becomes the same as X_{2V}, and if X_0 is infinite, $X_{2(2LN)}$ approaches $X_{2(LL)}$ as it should. Thus, depending on the type of fault and the value of X_0, the negative-sequence reactance effective for a particular case may have any value between the maximum value, denoted by $X_2=(X_d''+X_q'')/2$ and the minimum value, $X_{2V}=2X_d''X_q''/(X_d''+X_q'')$. It is also of interest to point out that $X_2X_{2V}=X_{2(LL)}^2$.

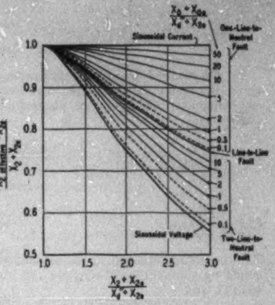

Figure 1. Correction factors for external reactance

The author suggests that the basic definition of X_2 should correspond to sinusoidal negative-sequence currents, namely $X_2=(X_d''+X_q'')/2$, and that the variation from this value for other cases should be allowed for separately, when correction is warranted. With this recommendation, I heartily agree. This value is the simplest and is the only one that is linear in X_d'' and X_q''. If external reactance is to be included, it may be added directly to this value of X_2, because X_d'' and X_q'' both will be increased by the amount of the external reactance. If any other of the five reactances is taken as basic, the inclusion of external reactance is much more complicated.

It is feasible to develop a general set of curves which give the correction factor by which the total value of nominal negative-sequence reactance, (X_2+X_{2e}), including any external reactance X_{2e}, is to be multiplied to determine the corrected or effective negative-sequence reactance for other cases. The correction factor may be expressed as a function of the parameters $(X_2+X_{2e})/(X_d''+X_{2e})=(X_d''+X_q''+2X_{2e})/2(X_d''+X_{2e})$, and $(X_0+X_{0e})/(X_d''+X_{2e})$, or some other combination of these same terms. Such a set of curves is shown in Figure 1 of the discussion.

It is evident that the correction factor differs little from unity unless X_2 differs considerably from X_d'', that is, unless X_d'' and X_q'' differ greatly. However, it is desirable to establish the basic relations in such a way that the corrections may be made easily whenever needed, and this is done most readily if the basic value of X_2 always is taken for sinusoidal negative-sequence currents. Since X_d'' and X_q'' are very nearly equal for turbine-driven generators and for salient-pole machines with an effective damper winding linking both axes, the correction will be small except for machines without damper windings or machines with a damper in only one axis.

Advances in Technique of Lightning Measurements

THEODORE BROWNLEE
MEMBER AIEE

Synopsis: Improved measuring equipment and refinements of technique contributed materially to the number and accuracy of lightning records taken, in a 4-year study, on a rural distribution system. Special shunts were developed to match the expected lightning currents to the voltage sensitivity of automatic cathode-ray oscillographs. Modifications were made in the method of initiation of the oscillographs and in their operation so as to get the greatest possible accuracy and to extend their period of unattended reliable operation. Refinements were made to increase the accuracy and speed of magnetic link calibrations and to permit the calibrating equipment to be operated from a low-power 115-volt supply. The 60-cycle after effects of lightning disturbances on the system were recorded by an automatic magnetic oscillograph.

NATURAL lightning is so variable in its intensity and duration, and so erratic in its choice of a time and place to strike, that plans for measurements must be made with extreme care. In considerable measure, the success of a lightning investigation depends upon the use of special equipment custom-tailored to fit the particular job. It is the purpose of the present paper to describe the equipment used in a 4-year project of this kind and to explain the reasons for the designs used. The results of successful operation of the equipment are given in a companion paper.[1]

Along with the lightning investigation, studies were conducted of short circuits recovery voltages, and methods of protection against overcurrents. These are described in other companion papers.[2,3] The present paper also reviews the main features of the oscillograph used to study recovery voltage.

Automatic Cathode-Ray Oscillograph Equipment

A desire to obtain additional information on long duration lightning was responsible for the development of the *HC-10-G1* oscillograph. The standard model has been described before,[4,5] but considerable modification was made for the present investigation. It is a relatively inexpensive instrument and runs for several hours with no attention. A number of them can be spaced at distances limited only by the time required for the operator to visit each one and set it in operation when a storm is expected.

Each oscillograph consists of two 3-inch cathode-ray tubes mounted close together, so that a single lens can be used to record both traces on a rotating drum. This drum takes a film $3^{13}/_{16}$ by 31 inches and rotates once every 0.7 second. After an exposure, the drum automatically shifts axially so that four distinct records can be obtained. Figure 1 shows a complete instrument and Figure 2 shows the position of the cathode-ray tubes, lens, and film-driving mechanism. The oscillographs operate from a 115-volt 60-cycle source. A simplified wiring diagram is shown in Figure 3. In it are incorporated several changes which make the oscillograph more reliable and accurate. Part of these changes were suggested by a previous discussion of this oscillograph.[6]

Seven of these oscillographs were used in the lightning investigation. Some of them recorded lightning-arrester current only, with different sensitivities for the two traces, so that accurately measurable deflections could be obtained over a very wide range of currents. In the others, one tube recorded arrester current and the other the current in the ground side of the transformer protected by the arrester. To avoid loss of records, in case of power interruption, each oscillograph was provided with a storage battery, charger, and dynamotor to convert from 12 direct volts to 115 alternating volts at 60 cycles. All this equipment and the shunts were mounted in steel housings on the lower part of the transformer pole, as shown in Figure 4.

Initiation and Operation

When a lightning storm seemed likely, the dynamotor and film-drum driving motor were started up in each oscillograph. Power was applied to the cathode-ray tubes, but with sufficient grid bias to leave the electron beams turned off.

Figure 5 (above). Volt-ampere characteristics of shunts

A. Connections and curves for transformer current shunt using two, three, or four series Thyrite disks
B. Connections and curve for lightning-arrester current shunt using four parallel Thyrite disks
D. Connection to deflecting plate of oscillograph
I. Connection to initiating terminal of oscillograph

R_{12} 10,000 ohms $R_{15}=12.5$ ohms
$R_{16}=250$ ohms $C_5=0.001$ microfarad

At the top of Figure 3 shunts are shown as used in an installation to record both lightning arrester and transformer currents. While the two shunts are not identical, their principles are the same. Their physical features are described later. They are needed to provide the necessary voltage to turn on the electron beams and to deflect them so as to produce a record on the rotating film. For brevity the word "initiate" is used to denote the turning on of the electron beams as soon as a predetermined current flows through either shunt. The chief elements of the lightning-arrester shunt are the parallel resistors, R_{13} made of Thyrite, and R_{15} which is wire wound. The net resistance is made sufficiently high to initiate the oscillograph at the desired minimum current. Since this voltage exceeds the requirements for the deflection plates of the cathode-ray tube, the deflecting voltage is taken from a tap on R_{15}.

Both cathode-ray tubes use the same accelerating voltage supply and initiate simultaneously. The capacitor C_1 is negatively charged to 1,300 volts. Before initiation, C_2 and C_4 also are charged to the same voltage, and the *FG17* thyratron is held nonconducting by virtue of its 22-volt negative grid bias. When a voltage appears across R_{13} and R_{15}, the 0.001-microfarad capacitor C_5 charges up through the 10,000-ohm resistor R_{12}. This combination has a negligible effect on the shunt voltage drop and has a low enough time constant so that the voltage on C_5 is substantially the same as the total shunt voltage for waves that can be recorded by the oscillograph. G_2 is a glow tube which becomes conducting at a voltage corresponding to the minimum current it is desired to record. As soon as G_2 becomes conducting, C_3 oscillates with the inductance *L*, and the oscillating voltage is applied to the thyratron grid through C_2. Hence, irrespective of the original polarity of the lightning, the thyratron bias is overcome and the thyratron becomes conducting. When this happens, the lower side of C_4 goes to ground potential. This changes the bias on both cathode-ray tubes, and the beams turn on. At the same time, C_4 discharges through the relay coil. For simplicity the film-shift mechanism and controls are omitted. Actually, the relay coil shown picks up time delay relays, which cause the film shift to occur after the recording and then to reset for the next operation. When the voltage on C_4 is reduced, the thyratron becomes nonconducting and C_4 charges up again, thereby increasing the bias on the cathode-ray-tube grids and turning off the beams about 1.4 seconds after initiation. This means the record can last for two full revolutions of the drum, but the beam intensity gradually is reduced so that it is not difficult to interpret a record lasting from 0.7 to 1.4 seconds.

The rotating film-drum shaft is held in position by a nut on the threaded drive shaft. Ordinarily, the nut rotates on the shaft and the drum has no axial motion. After each record is taken, a solenoid moves an arm out which catches a pin in the nut and stops its rotation. Then the rotation of the shaft causes the nut and film drum to move downward. The time delay relays are adjustable to control the length of time the solenoid arm engages the pin. When set as in the lightning investigation, the axial motion starts five seconds after initiation and lasts for seven seconds. There is no period during which a record cannot be taken, for a second in-

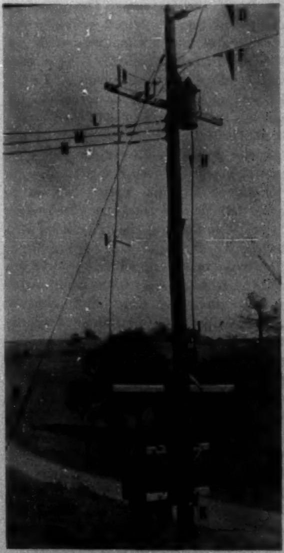

Figure 4. Typical pole installation with magnetic links and cathode-ray oscillograph

itiation can occur before the beam goes off, but, of course, the second record can be superimposed or but slightly shifted from the first, if initiations are not spaced by at least 12-second intervals. Originally, when the nut reached the end of its travel, a limit switch shut off the battery supply to the dynamotor to prevent mechanical damage. This might occasion the loss of an important record, so the solenoid arm was reshaped so as to leave the nut free to rotate after the third shift (and fourth record). Hence, there might be several superimposed records in the fourth position, but no records were lost because of run-down film drums.

The initiation from the transformer shunt uses the same inductance L as described previously, but an air gap G_1 is used instead of the glow tube G_2. This takes a higher voltage to spark, but was necessary because the current in the transformer increases gradually, and the glow voltage on the tube would prevent oscillation. The lightning-arrester current increases abruptly after the lightning-arrester sparks over, and, for steep wa[illegible] the glow tube has a sparkover vol[illegible] sufficiently above the steady glow voltage to insure oscillation.

Maintenance of Constant Sensitivity

Each oscillograph derives its power from a 12-volt battery through a dynamotor D, as shown schematically in Figure 3. R_{11} is a field rheostat to control the dynamotor speed. As the battery voltage runs down, the dynamotor voltage drops in proportion. This in turn changes the cathode-ray beam voltage and the sensitivity of the oscillograph. In addition, when C_4 is discharged through the thyratron, the voltage on C_1 is reduced for a few seconds until C_4 charges up again. By using a large value of five microfarads for C_4, the reduction is but eight per cent. The resultant small change in sensitivity is the same for every exposure and can be allowed for in the analysis of the oscillograms.

The change caused by reduced charge on the batteries was practically eliminated by using a ballast-tube resistor R_8 in series with the transformer T which charges up C_1. Without this ballast tube, the voltage on C_1 drops about 15 per cent as the battery becomes discharged; while with the tube, the change is about one per cent. The sturdy resistor R_5 has the same resistance value as R_8 at average operating conditions for R_8 and serves a dual purpose. Normally, when S_8 is closed to start the film motor M, S_6 is already in the left position, and R_5 acts as a current limiting resistor for R_8 while C_1 charges up. Then, when C_1 is charged up, S_6 is thrown to the right and R_5 is short-circuited. To avoid a loss of record, a Novalux cutout CO is used which becomes conducting if R_1 becomes open; then, when S_6 is thrown to the right, power is fed to the transformer through the cutout and R_6. During normal operation the battery chargers are left on continuously, and the oscillographs will run about 20 hours. If there is a power failure they will operate for four hours.

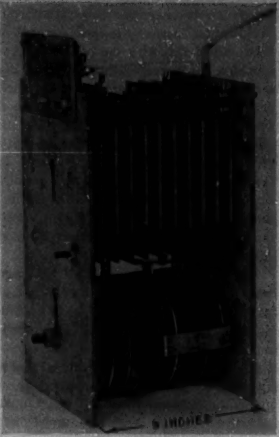

Figure 6. Combination shunt

Shunts

It was desired to measure the lightning currents flowing through transformers and lightning arresters on a 7,200-volt grounded system. It was relatively simple to insert shunts between these devices and the neutral conductor which is grounded at every pole. The desirable qualities for these shunts are enumerated here with explanations of how well these qualities were attained.

1. Ample discharge capacity. This was secured by using liberal-sized components with adequate clearances and insulation. The entire shunt structure was immersed in oil.

2. Stable characteristics. The resistor materials were carefully chosen. Laboratory measurements of the direct current and impulse characteristics were taken before and after the investigation with excellent agreement.

3. A nonlinear volt-ampere characteristic is desirable so that an extended range of currents can be measured with readable deflections. However, for best accuracy, the voltage range should not be compressed beyond that necessary to cover the required current range. Some special low-exponent Thyrite was used, shunted by comparatively high linear resistors. Figure 5 shows the characteristics of these shunts.

4. Accessible taps so that the current range to be studied can be varied if necessary. Since the voltage required for initiation is more than adequate for beam deflections, taps are provided on the linear resistance portion of the shunts. An entire shunt can be removed easily from its tank for tap changing.

5. Low inductance. The inductance was kept as low as possible. The inductance drop is negligible for currents that can be recorded by the oscillographs.

The lightning-arrester and transformer current shunts are mounted in a single frame with a common ground, as shown in Figure 6. The complete unit is set in a distribution transformer tank about 12 inches in diameter.

Calibration of Oscillograph

It is highly advantageous to be absolutely certain that the initiating and measuring circuits are in good condition. Hence, provision is made to check these circuits after the final installations. When switch S_1 of Figure 3 is thrown to calibrate position, the line-deflecting plates and initiating circuits of both tubes are connected to an octal socket at the rear of the oscillograph housing. A special calibrating box can be connected to any of the oscillographs.

Provision is made to supply to the deflecting plates 35 or 70 rms volts at 60 cycles, or 22.5, 45, 67.5, 90, or 112.5 direct volts. A dry cell, push button, and small step-up transformer are mounted in the same box and are used to check the initiation of either circuit. Suitable switches are provided on the box, so that all the checking can be done quickly, efficiently, and easily.

Testing with Impulse Generator

At the start of each season, an additional over-all check on the shunts and oscillographs was made, using a portable impulse generator which was discharged directly into the lightning arrester at each location. A 0.33 microfarad capacitor bank charged to 90 kv was used, with sufficient series impedance to give a crest current of about 3,000 amperes. The feeling of assurance that all equipment was ready to operate correctly was certainly well worth the expense of thorough checking.

Magnetic Link Calibrating Equipment

The use of magnetic links for measuring lightning currents is well known and has been described in previous articles.[5,6] In the lightning investigation, links were bracket mounted at spacings of 13/16 and $2^{3}/_{16}$ inches from the conductor with both links lining up with the flux lines which encircle the conductor when it carries current. With these spacings, and the technique described hereafter, crest currents in the range of 100 to 30,000 amperes could be measured with an accuracy of around 10 per cent. Figure 4 shows a typical multiple installation with 10 brackets, identified by letters, on a pole at the end of a feeder. Additional brackets were used in locations where there were more conductors arriving at, or leaving the pole. In addition to some 30 multiple installations like these, there were about 1,300 brackets, one per pole, to measure lightning arrester current.

The usual surge-crest ammeter is a compact and easily carried instrument which can be used anywhere to measure the magnetism retained in the links. However, the individual links, while comparatively uniform at medium degrees of magnetization, vary considerably at low and at high degrees of magnetization. For the lightning investigation it was decided to use the ballistic galvanometer method of calibration developed by McEachron and McMorris.[7] In this discussion of magnetic links, the word "calibration" means the measurement of the retained flux with the ballistic galvanometer, using average link curves to determine the current and reversal which produced the retained flux. This method was used for the 1,300 installations to obtain statistical data on the probability of strokes of various magnitudes. It saved considerable time and was permissible for data of this sort, since the resultant curve is little affected by variations about the average in individual links.

For the 30 multiple installations it was desired to obtain much more precise measurements. Each pair of links was given an "individual calibration" meaning that, after galvanometer measurement, the links were demagnetized and a cut and try process of remagnetization applied to find out what kind of field must have produced the original retained flux.

Special Magnetic-Link Calibrating Table

In Figure 7 is shown a special table first used in the lightning investigation for magnetic-link studies. It is designed for convenience, speed, and accuracy in the calibration and demagnetization of links, and especially for the rapid individual calibration of pairs of links.

Calibration of Links

A link which is magnetized, as shown by a compass indicator, is first calibrated by rapidly withdrawing it from the magnetizing coil, which is in series with the ballistic galvanometer and a 4-position adjustable attenuator. The attenuator varies the sensitivity and gives approximately critical damping on all positions. This method is very sensitive; the coil has to be swivel mounted and set with the axis perpendicular to the earth's field to avoid errors. When the deflections for a pair of average links have been measured, curves can be used to determine the crest current and per cent reversal.[6]

Demagnetization of Links

The demagnetizing coil is similar to the measuring coil, but it is larger and is wound with coarser wire. It is connected to the 115-volt a-c supply through a push button and also is swivel mounted. A link is demagnetized by inserting it in the coil and then drawing it out slowly while the push button is held down. Unless the link is withdrawn axially with a motion perpendicular to the earth's field, it will not become completely demagnetized.

Individual Calibration of Links

The individual calibration of links is considerably slower than a curve calibration, but its accuracy is much better, and it was absolutely necessary to obtain the good correlations found in the lightning investigation. It is not practical to use currents and link spacings as encountered in the field, but substantially the same fields can be produced by coils with currents of 10 amperes or less. For some years such a coil has been used in connection with a d-c generator. However, about 5 kw are required to saturate a link, and, in the few seconds required to adjust and to read the current, the coil overheats. For the calibration table a new method was used which has the following improvements:

1. It operates from 115 alternating volts.
2. It takes very little power.
3. The coil overheating is eliminated.
4. Ample time is available for meter reading.
5. The inner and outer links can be calibrated simultaneously with any ratio of currents in the two coils.

Instead of using steady direct current for calibration, the coils are energized by capacitor discharges, with special care taken to prevent any reversal during the discharge. Figure 8 shows the circuit used in the special table. For any fixed values of *E*, *C*, *R*, and *L*, the crest current can be calculated—the current is always proportional to the voltage which can be read on the voltmeter. By changing the resistance in series with the outer link coil, the ratio of currents in the two coils can be maintained at any value corresponding to the spacings of the links from the lightning conductor. The coils are mounted on the underside of the rear table cover, with conical depressions in the cover to facilitate inserting and removing the link. They are located about three feet apart and at some distance from other equipment to avoid interaction with the calibrating fields. The coils are wound on a spool of 3.75-inch diameter and 1.125 inches wide. A total of 2,080 turns, in 52 layers, is used. The average coil diameter is 5.30 inches. The field strength on the axis can be calculated, and, over the active link length, the average field strength is within three per cent of the maximum field strength at the geometric center of the coil. The coils are large enough so that the presence of the link does not appreciably affect the total

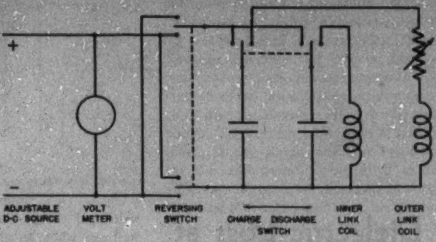

Figure 8. Simplified wiring diagram of impulse calibrating circuit for magnetic links

flux. As a safety precaution, the power pack and all live parts are interlocked so that the power supply must be interrupted and the capacitor banks discharged before any of the circuits are made accessible.

The Automatic Oscillograph (Duddell Type)

The automatic oscillograph was used in the studies reported in the three companion papers. It has been described fully before;[8,9,10] only the main features are reviewed here. It records six voltages or currents on a roll of photographic paper 4.5 inches wide and 200 feet long. The oscillograph is equipped with a mirror to provide the initial sweep motion and will record all but one-half cycle of a disturbance whose instantaneous current exceeds a predetermined value. The recording continues as long as the disturbance persists, at a rate of the order of one foot per second. The companion papers[1,3] give examples of the oscillograms.

In the present investigation, one or sometimes two of these oscillographs were used to record feeder phase and neutral currents near the substation or at the fault. Current transformers were inserted in all 3-phase wires, and another was inserted in the neutral. The secondaries of these transformers were all grounded on one side. An oscillograph vibrator was connected in series with each of the nongrounded terminals. The four vibrators were connected together on the ground side, but had the trip coil of the oscillograph inserted between the common point and ground.

The transformers were connected so that the current in the neutral added to the phase-wire current to facilitate the tripping. The sensitivity of the trip coil was such that a record would be taken if the current in a phase wire reached 40 amperes crest. The trip coil was shunted by a small Thyrite resistor to protect the coil and to keep down the burden on the current transformers.

Rotating-Drum 3-Element Cathode-Ray Oscillograph

The 3-element cathode-ray oscillograph used to study recovery voltages[2] was described previously by Rudge and Wade.[11] A rotating-drum-type film holder is used, with a top speed corresponding to 25 microseconds per millimeter. The oscillograms are obtained by photographing the phenomena on the fluorescent screen of the cathode-ray tube, using $f2.0$ lenses and 35-millimeter film. The magazine film drums hold 100 feet of film; means are provided for cutting off the exposed portions after each test. In the recovery-voltage tests, the oscillograph was coupled to the lines under study by compensated voltage dividers using resistance and capacitance elements. Typical oscillograms are shown in a companion paper.[2]

Conclusion

The findings of the three companion papers were made possible by the diligent efforts of a number of people, and also by the proper functioning of the equipment they used. The true value of this equipment is best demonstrated by the important disclosures in these papers.

The Measurement of Dielectric Loss at High Frequencies and Under Changing Temperature

J. B. WHITEHEAD
FELLOW AIEE

W. RUEGGEBERG
ASSOCIATE AIEE

DIELECTRICS of all types are highly sensitive to change of temperature, dielectric losses especially rising rapidly with rise of temperature. Thus dielectrics to be used as insulators must be sharply limited as to dielectric loss and rise of temperature. On the other hand high dielectric losses are advantageous in composite materials requiring heating for curing or thermosetting. Industrial dielectric heating by high electric frequency, therefore, involves a new viewpoint as to desirable dielectric behavior, and demands a new survey and new methods of measurement of dielectric properties.

This paper describes a method of measuring the properties of a dielectric at any point in a high frequency heating cycle. Some of the results of measurements on several dielectric materials are given, with some general comments thereon. The paper however does not give complete numerical data on the materials studied, nor does it aim to analyze their behavior in terms of dielectric theory. The work was done in the School of Engineering of The Johns Hopkins University under the auspices of the Armstrong Cork Company.

Present Available Methods of Measurement

Of present available methods of measurement of dielectric properties under alternating stress all are limited apparently without exception to the steady-state condition with temperature constant. This applies also to a number of methods for frequencies in the megacycle range best suited for dielectric heating, such as American Society for Testing Materials shunted susceptance method,[1] bridge-type Q-meters, and others.

For two main reasons such methods are not suitable for following the dielectric through a high frequency heating cycle:

1. The low value of applied stress.
2. The difficulty of maintaining constant temperature during measurement.

An appreciable value of stress is necessary to liberate the internal dielectric losses. Moreover, once initiated, these losses increase with time over an appreciable period, thus precluding any effort to maintain constant temperature. A method is necessary in which temperature rise is caused by applied stress, and in which applied stress, current, and temperature, and also power input, may be measured at any stage in the heating cycle.

Method of Measurement

The method of measurement, described in a previous paper[2] is based on the conventional vector diagram of component voltages when an alternating electromotive force of any frequency is impressed on a cell containing a dielectric. The thermally-insulated cell is again shown in Figure 1, and the simple electric connections, with vector diagram of voltages, in Figure 2. In a heating run the current I in the sample is read directly by the thermoammeter F, the applied voltage E_0 by a vacuum-tube voltmeter, and the temperature at any point in the sample by thermocouples T, T, in Figure 1. Separate measurements are made of the impedance voltages E_z, E_{zr}, E_{zx}, of the ammeter and connections. Vector IR, however, cannot be measured directly.

Complete solution of the vector diagram, for dielectric constant, loss, and power factors, is obtained by finding the value of the vector IR, in which R is the effective resistance of dielectric loss. This vector cannot be measured directly, but its value is obtained by a separate calibration of the cell containing a second identical sample in which are imbedded thin high resistance grids (nichrome) heated with continuous current. Internal temperatures are read from thermocouples located as in the a-c heating run. After a

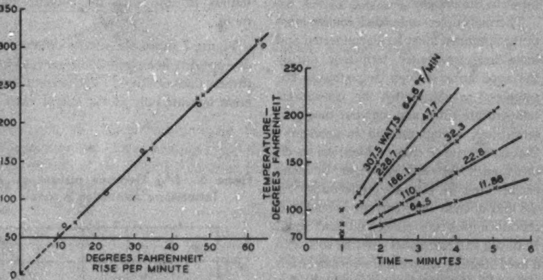

Figure 3. D-c calibration curves of sample in test cell

brief initial period the temperature of the sample increases linearly with time as shown in Figure 3 for several values of heating current.

Each of these curves in its linear portion represents a uniform rise of temperature, that is, a temperature-time gradient of so many degrees rise per minute, corresponding to a uniform supply of energy in watts due to the constant heating current. The family of heating curves may be combined in one curve showing heating watts as function of rate of rise of temperature, also shown in Figure 3. It will be noted that this curve is also a straight line up to 50 or 60 degrees Fahrenheit per minute; it passes through or near to a zero-point of no energy and no temperature rise.

Figure 4 shows the average location of the heating curves of two variations of the same material, each mixed with a binder, put under pressure in the cell of Figure 1, and heated by applying electric stress of 0.8 volt per mil at 10 megacycles. Temperature, current, and voltage can be read at one-half minute intervals. A tangent to the heating curve at any point gives the rate of temperature rise at that point. The corresponding rate of energy input, that is, watts, may be taken from the d-c calibration curve. If *R* is the effective resistance of dielectric heating, then the d-c watt input may be written as I^2R, in which *I* is the measured high-frequency current corresponding to the point in question on the heating curve. The vector *IR* of Figure 2 is now known and all quantities computed readily.

Improved Test Cell for 30 Megacycles

The duration of the heating cycle, that is the time required to reach a definite curing temperature, may be shortened by increasing the rate of energy input. This may be done by increasing the applied voltage, increasing the frequency, or by reducing the mass (for example, the thickness) of the sample. In the improved cell shown in Figure 5, all of these means have been employed. In the earlier work at 10 megacycles the duration of the heating cycle was from four to five minutes. In the present work cycles, from 20 to 40 seconds for temperatures up to 250 to 300 degrees Fahrenheit were common.

In the cell of Figure 5, the following modifications of the earlier cell may be noted:

1. *A* and *A* are duplicate samples, each five inches in diameter and 1/4 inch thick. *B* is the high-voltage electrode of nichrome foil, $3^1/_2$ inches in diameter. *G* and *G′* are the low-voltage guard ring electrodes, $2^1/_2$ inches and $3^1/_2$ inches in diameter, and also of nichrome foil. With these changes the cell has been carried to 1,200 volts, 30 megacycles, giving an applied stress of 4.8 volts per mil, which results in heating cycles from 16 to 40 seconds for the materials being studied.

2. The increase to 30 megacycles steps up markedly all electrostatic inductive disturbances. Complete and individual screening of all electrode connections and of back faces of electrodes becomes necessary. A metal housing completely enclosed the ammeters, *F*, *F*, and was tied to the immediately adjacent ground connection of the 2-kw Westinghouse oscillator by heavy copper strap. The high-voltage terminal of the generator and its short connection to the high-voltage terminal of the cell also were enclosed in double screening connected to ground.

3. In order to ensure uniformity of temperature in the test sample, it was found necessary to preheat the electrodes. This was done by inserting thin nichrome heating grids in the insulating backing of the low-voltage electrode and using a duplicate sample on the back face of the high-voltage electrode (see (4) below). A necessary condition in this electrode preheating was that no heat should pass from electrode into the sample. Test for this condition was made by thermocouples in the interface of sample and electrode and in the interface between back of electrode and adjacent insulation. As long as the former showed the higher temperature, the heat-flow was outward only. Subject to this restriction electrode preheating has the effect only of increasing the thermal resistance of the electrode insulating supports. Figure 6 shows that only after 20 seconds preheating of the electrode did any heat arrive at the outer surface of the sample. It was also found that throughout the a-c cycle, this surface was hotter than that between electrode and supporting insulation. The figure also shows a typical variation of temperature through the thickness of the sample.

4. The insulating supports of a high-voltage electrode are obviously subjected to electric stress and dielectric heating. The resulting losses are an additional

Figure 4. Heating curves of granulated cork

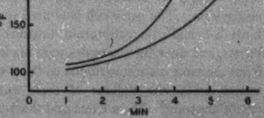

Figure 5. Test cell for 30 megacycles

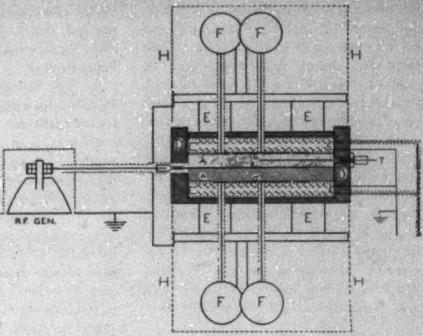


load on the generator, but cause no error in the measurement of loss in a sample. They do, however, at and above 30 seconds cause appreciable heating of the electrode insulating backing, and so may be utilized as electrode heating to help maintain uniform temperature in the sample (see (3) above).

The problem of the adjustment and measurement of this external electrode heating was met in the final form of cell by using two identical samples with a single or common high-voltage electrode between them, and with duplicate measuring electrodes and instruments as shown in Figure 5. In this way the high-voltage electrode is supported by the specimen itself, the temperature on both sides is the same, and thus results a maximum efficiency of electrode heating without either gain or loss of heat for either sample. As this balance obtains throughout the heating cycle, there is no necessity for preheating the high-voltage electrode.

5. In assembling the sample in the test cell, it was found necessary to use thin paper disks between sample and electrodes, and between sample and heater grids in the d-c calibration. Consequently part of the measured a-c input power goes into heating the electrodes and the paper disks. Separate measurements were made on the paper disks, and the heat to raise the mass of the electrodes could be computed readily; these two excess heating losses were deducted from the total a-c input values (at any desired temperature) as obtained from the d-c calibration. The same cell was used for both a-c and d-c calibration measurements, and since the electrodes were made from the same nichrome ribbon as the d-c heater grids, the volume of each was nearly the same. The a-c test and the d-c calibration samples were closely identical. The small excess losses referred to before were always a small fraction of the total input to the sample.

Thermocouples imbedded in the mass of the specimen must be disconnected and have low-capacitance terminals during the application of high frequency to the samples. Consequently for continuous temperature-time and current-time observations, a step method is necessary; that is, a series of runs on identical specimens, each one running longer, by some chosen interval, than its predecessor. At the end of each step, current is read and thermocouples are connected and read. Both cell and electrodes must be cooled to a fixed starting temperature between each step. Final temperatures for each step may be read with a needle thermocouple if the cycle is long and the material permits. However, for cycles as short as 30 or 40 seconds and a sample of small volume, temperature changes are rapid when voltage is removed and a faster temperature reading is necessary. A satisfactory solution was found in a pair of spring-operated contacts for the leads of imbedded thermocouples, and a Brown rapid temperature recorder. With this arrangement, temperatures could be read and recorded in one to two seconds after the removal of high-frequency voltage.

Experimental Accuracy

The accuracy of instruments and observations of the electrical quantities is better than two per cent, and this is well within the percentage variations of the materials both as furnished and after conditioning. It is believed that much the same may be said as to the temperature measured by the Brown recording instrument, with which temperature is read within one or two seconds after removal of the high-frequency voltage of the test.

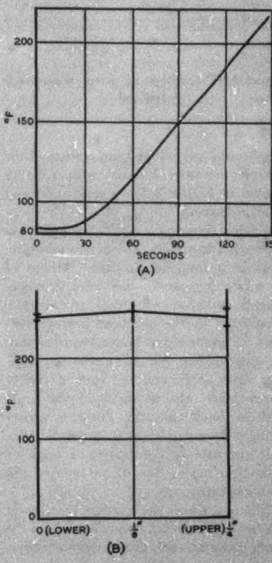
Measurements

Measurements were made on a number of powders and preforms. In the preform the powder is compressed so that it retains a definite shape, in our case a disk, five inches in diameter and one-eighth inch thick.

Dry Materials. The normal heating or temperature-time curve of a dry thermosetting material is concave upwards. The corresponding current-time curve at first increases, then more slowly and finally passes through a maximum and decreases. The result of this relationship is a curve of loss factor and one of dielectric constant, both increasing at first, and each then passing through a maximum approximately in step with the current maximum.

Figure 7 shows the results on a certain dry powder, heated at 30 megacycles and three values of stress. The current maximum appears only at the lowest value of

Figure 6. (A) Electrode preheating. (B) Temperature distribution in sample



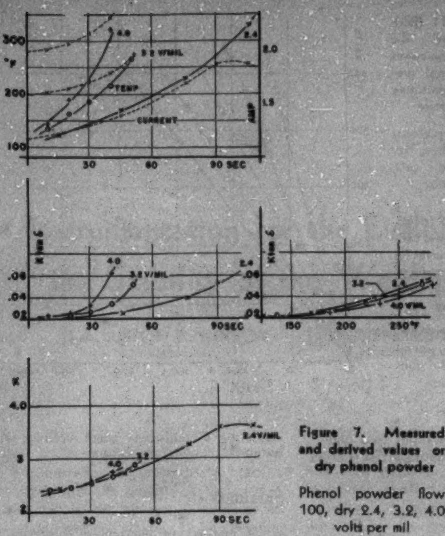


Figure 7. Measured and derived values or dry phenol powder

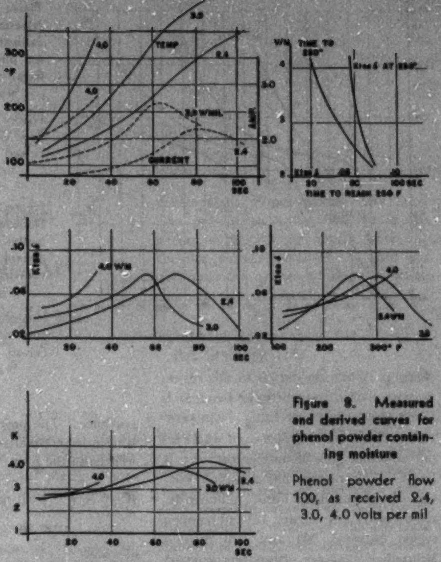

Figure 8. Measured and derived curves for phenol powder containing moisture

Phenol powder flow 100, as received 2.4, 3.0, 4.0 volts per mil

stress. A still lower value would be necessary and a longer heating cycle to bring out all of the behavior outlined in the foregoing paragraph.

Materials Containing Moisture. It is a long process to dry powders and preforms completely, and a relatively small amount of residual moisture causes an important variation of the behavior just described. In such cases the maxima of current, loss factor, and dielectric constant all appear, but earlier and in more pronounced character than in the dry specimens. Thus Figure 8 shows the results taken from a powder in the condition as received from the manufacturer and without preliminary drying. A somewhat extreme case is shown in Figure 9, for a preform not completely dry. In this case a loss factor of 0.2 is reached while the water is being driven off. In other cases, known to contain more moisture, much greater values of loss factor have been found.

The presence of water in a test sample is clearly shown by the d-c calibration curve. Figure 10 shows the measured and derived calibration curves of a dry powder, and Figure 11, the measured calibration curves of a preform with a moderate amount of absorbed moisture. In the latter, after initial temperature equalization, the curves are approximately linear between 110 and 200 degrees Fahrenheit. Between 200 and 220 degrees the curves flatten out sharply, and most of the heat input is expended in vaporizing the contained moisture. Above 220 degrees the rate of temperature rise again increases

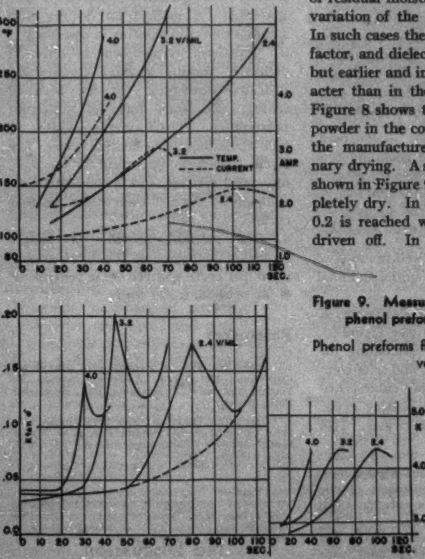

Figure 9. Measured and derived curves for phenol preform containing moisture

Phenol preforms flow 60, dry 2.4, 3.2, 4.0 volts per mil

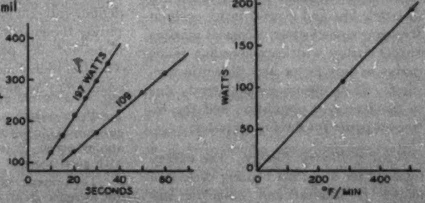

Figure 10. D-c calibration curves for dry phenol powder

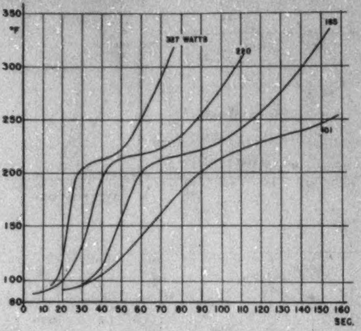

Figure 11 (left). Measured d-c calibration curves for phenol preform containing moisture

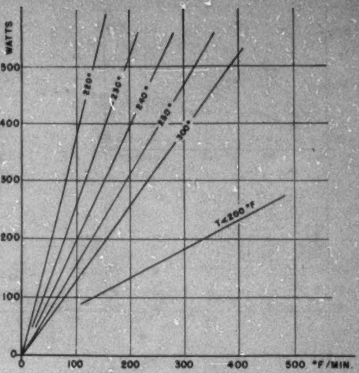
Phenol preforms flow 60, as received d-c calibration

Figure 12 (right). Derived d-c calibration curves for phenol preforms containing moisture

Phenol preforms flow 60, as received d-c calibration



sharply. While the curves in this region do not at once resume linear form, it is found that at any one value of temperature the derived curve between watts input and time rate of temperature rise is linear. This means that a sample containing moisture has a family of linear derived curves (see Figure 12) and an open region between 200 and 220 degrees Fahrenheit. Under alternating current conditions in passing through this range, there is a large increase of loss factor. (See Figure 9.)

Dielectric Absorbtion as Heating Process. We have seen that in a dry powder under stress, 2.4 volts per mil, a maximum of current appears only after 100 seconds, whereas at 4.0 volts per mil, the temperature rises to 245 degrees Fahrenheit with 20 to 25 seconds at an approximately linear rate and without evidence of current maximum; loss factor, and dielectric constant remain constant.

These two types of behavior indicate that, since even the dry dielectric is complex, classical dielectric absorbtion may be present as a mechanism of heating. This phenomenon involves no molecular changes, is faster than molecular polarization, and simply heats the dielectric by an integrated i^2r process.

The presence of moisture increases the dielectric absorbtion and corresponding dielectric loss and gives a faster cycle at the same applied stress. Current maxima appear earlier with corresponding rising curves of loss factor and dielectric constant. These effects are apparently due to the increased absorbtion and the increased power for driving off water.

Input of Electric Energy. The energy required for a normal heating cycle is a matter of interest and economic importance. The power input to a dielectric subjected to alternating stress is often written in the form

$$W = 0.55\left(\frac{E_0}{d}\right)^2 fK \tan \delta 10^{-12}$$

watts per cubic centimeter (1)

in which

$\frac{E_0}{d}$ = applied stress, volts per centimeter
f = frequency, cycles per second
K = dielectric constant
δ = loss, or phase defect angle

It has long been known that for a complex dielectric K and δ may vary over wide ranges with change of temperature. Consequently equation 1, to be applicable for computing the energy input to a dielectric heating cycle must be written

$$\int_{t_0}^{t_T} W dt = 0.55\left(\frac{E_0}{d}\right)^2 \times f \times \left[\int_{t_0}^{t_T} K \tan \delta dt\right] 10^{-12}$$

watt-seconds per cubic centimeter (2)

in which $K \tan \delta$ is a derived function of time, and t_0 and t_T are the initial and final times of the heat cycle.

The computed curves of loss factor, $K \tan \delta$, as function of time (see Figure 9), afford a ready means of evaluating the definite integral indicated, and so of computing the energy input per cubic centimeter for any particular heating cycle. This has been done for many cases. Two results may be mentioned:

1. The energy input to reach a given temperature is generally independent of the applied stress, as is to be expected in a cell with good thermal insulation.
2. The presence of absorbed moisture does not increase greatly the energy input, thus indicating a relatively small volume of water.

Summary

1. A method of measuring the properties of a dielectric while its temperature is changing has been developed and applied to certain thermosetting materials under high-frequency heating.
2. The presence of absorbed moisture in small amounts has a pronounced influence on the dielectric properties of such materials. A method for dealing with samples containg moisture is described.
3. Two basic phenomena are active in dielectric heating at high frequencies: dielectric absorbtion (in the Maxwell sense); and some form of molecular polarization. The former is evident in high-stress short-time heating cycles. The latter is the more important for the thermosetting process, and is completely developed in longer lower-stress heating cycles.
4. The method provides a simple means of determining the total energy input per cycle and per cubic centimeter of the material under study.

Instrumentation for the Evaluation of the Stability of the Welding Arc

LAURISTON P. WINSOR
MEMBER AIEE

L. McDONALD SCHETKY
NONMEMBER AIEE

ROBERT A. WYANT
NONMEMBER AIEE

THE importance of the stability of the welding arc on both the ease of welding and the quality of the weld is fully recognized by everyone concerned with arc welding, whether he be a welding engineer or operator. The term arc stability is used widely by the industry, although too often it is loosely or poorly defined. Qualitatively, arc stability is understood to mean the ability of an arc to remain fixed in position, with uniform electrical characteristics, and uniform flow of heat to the weld. The arc should have no tendency to become extinguished and should have ample ability to recover from the frequent short circuits introduced by the deposition of weld metal. Quantitatively, it is difficult to express arc stability in terms that permit explicit definition or numerical measurement. Because of this, many decisions, such as the evaluation of the quality and performance of welding electrodes, machine characteristics, and recommended voltage and current ranges, are left largely to the personal opinions of expert welders. Their judgment is frequently supplemented by visual examination of the welds, metallurgical studies of the weld metal, and mechanical tests.

During the past two years, the Welding Laboratory at the Rensselaer Polytechnic Institute, under the sponsorship of the United States Navy Bureau of Ships, has been engaged in the development of instrumentation for the study of arc stability. A number of instruments have been developed, each of which measures some characteristic or parameter of the arc which is thought to influence arc stability, and which might serve as an indication of the degree of arc stability. These instruments have been designed to be simple in operation, easily read, readily reproducible, and portable enough to be taken from one laboratory to another and into the field to make measurements under actual welding conditions.

A rather extensive program of research utilizing the new instrumentation is now in progress in the laboratory. A general discussion of the scope of the over-all program, along with a review of the preliminary experimental data obtained, has been described in a recent publication.[1] The welding arc is being studied for a wide range of variables, such as electrode type, core and coating composition, arc current and voltage, and circuit characteristics. The new instrumentation is being supplemented by more conventional studies, such as depth of weld penetration, spatter loss, and visual observation of the arc and weld. When the results are assembled and correlated, it should be possible to make better evaluation of the worth of the newer instrumentation.

These results may reveal the measurements of one of these instruments to be more significant than the others, and lead to the adoption of that instrument as a major tool for further work. Or, they may show the need for modification of the present designs or even for further development along entirely new lines. The present paper is therefore in the nature of a progress report describing the instruments developed to date and outlining the research program being conducted to evaluate their merits.

Electrical Approach to the Study of Arc Stability

The over-all stability of the welding arc should be considered from three points of view: spatial; thermal; and electrical. These three stability characteristics are so interrelated that changes in spatial position or thermal equilibrium should be reflected in the electrical characteristics. Study of the electrical stability of the arc can therefore be used as one approach to the measurement of the total arc stability. This approach has been used as the basis of the instrumentation to be described. The electrical quantities that can be studied are the arc voltage, arc current, and power consumed. Typical arc voltage, current, and power characteristics of three representative types of electrodes on straight polarity direct current are shown by the oscillograms in Figure 1. All three were taken using the same welding head and arc welding generator. Figure 1(A) for a lightly coated (*class E-6045*) electrode and Figure 1 (B) for a heavily coated (*class E-6012*) electrode are representative of electrodes which deposit weld metal in the form of molten drops. Frequent short circuits are observed to occur when the metal globules being deposited momentarily short circuit the arc. These short circuits are accompanied by transient variations in the arc voltage, current, and power. The number, duration, and random distribution of these short circuits depend on many variables, such as electrode coating, arc length, arc current, and circuit characteristics. Between the short circuits, the arc voltage, current, and power values are subject to appreciable random fluctuation introduced by many factors such as motion of the arc, nonhomogeneity of the electrode core and coating, changing composition of the gases and vapors

within and about the arc, formation and motion of molten drops on the end of the electrode, and turbulence in the crater. Figure 1 (C) for a *class E-6020* electrode is representative of those electrodes which deposit metal in the form of a spray of fine droplets. Here the short circuits introduced by droplet deposition of metal are entirely absent leaving the voltage and current characteristics with only the irregular fluctuations about the mean. Many oscillograms have been recorded of the characteristics of several electrode classes, over a wide range of arc current and voltage, and with both straight and reverse polarity. The electrical characteristics observed were all found to follow the same general pattern illustrated in Figure 1. The disturbances observed can be divided into two classifications for systematic study: fluctuations in the magnitude of arc voltage and current; and short circuits introduced by the deposition of metal.

Two approaches to the quantitative study of these disturbances were considered. One was a detailed study of the instantaneous variations in arc voltage, current, and power, placing emphasis on such characteristics as recovery from short circuits and the transient variations in the current and burning voltage. Since this approach would lead primarily to an oscillographic investigation, the study time would be limited to the relatively short duration of an oscillogram. The other approach was a statistical study of the variation of these parameters over a relatively long period of time, such as the deposition time of a 14-inch electrode. This seemed preferable for the present research program in which the arc is being studied under practical welding conditions. Owing to the time limitation imposed by the oscillograph, other forms of instrumentation were sought. Careful investigation of techniques to obtain the required information by direct measurements led to the development of a number of new instruments for arc studies. These are instruments to count the number of short circuits in the arc, to measure the proportion of the time the arc is short circuited, and to measure the rms deviation of the arc voltage and current.

The Short Circuit Counter

The rate of occurrence of short circuits in the arc stream is very irregular and usually of too high a frequency to permit counting directly with an electromechanical counter. The duration of the short circuits also is very irregular and often of too short duration to provide sufficient energy to operate a mechanical-type counter. Both of these obstacles are overcome easily by electronic counters because of their high speed and low energy requirements. Electronic counters have now reached a high degree of development due to the widespread requirement for counting pulses from radiation detectors and other pulse-making devices. Many satisfactory electronic counters are commercially available. Their application to the present problem, however, was handicapped because the pulse required to initiate the counter could not be obtained directly from the arc voltage.

The development of the short circuit counter hinged on the design of a satisfactory short circuit detector. Several requirements had to be satisfied. First, the detector should not be actuated by short circuits whose duration are less than a definite preassigned time. This limitation was imposed to eliminate counting extremely high-frequency voltage dips too short to be shown by the magnetic oscillograph. The detector should be actuated once, and only once, by each short circuit to be counted, regardless of its duration, and be reset immediately after removal of the short circuit. This condition eliminated a number of possible detector circuits which would be reset after a fixed time delay. Finally, the detector should not be sensitive to sharp changes in voltage, such as might be introduced by transient variations in burning voltage. This led to the requirement that the voltage actually drop to the short circuit value to be detected.

All of these requirements were met by the detector shown in elementary form in Figure 2. The basic circuit is a parallel inverter consisting of the thyratrons T_3 and T_4, current limiting resistances R_1 and R_2, and the commutating capacitor C. When the arc is burning, tube T_3 is conducting, while the negative arc voltage impressed across the capacitor

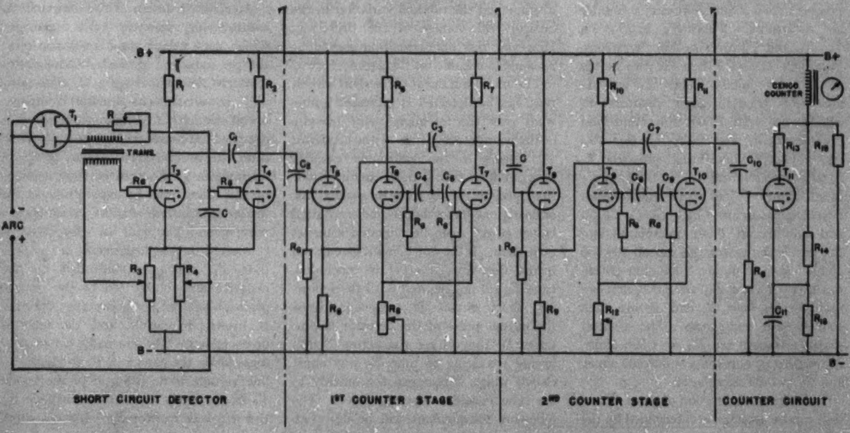
C holds the grid of T_4 more negative than the critical grid potential. When a short circuit occurs in the arc, the "arc" voltage drops to a low value, allowing the capacitor C to discharge through the resistance R and rectifier T_1. After the lapse of a short interval of time, determined by the time constant RC, the negative grid potential on tube T_4 is reduced sufficiently to cause the tube to conduct. Since the commutating capacitor C_1 was previously charged to the difference between line potential $B+$ and the relatively small burning potential of tube T_3, the sudden drop in the anode potential of tube T_4 caused by conduction suddenly reduces the anode potential of tube T_3 to a high negative value and extinguishes the tube. The capacitor C_1 then discharges and recharges with opposite polarity through resistance R_1 and thyratron T_4, thereby raising the anode potential of thyratron T_3 exponentially to full line value.

When the arc is re-established following the short circuit, capacitor C charges immediately through rectifier T_2 and the primary of the grid transformer. The transient surge of charging current through the transformer induces a momentary voltage peak across the secondary which fires tube T_3 and simultaneously extinguishes tube T_4. The subsequent reapplication of anode potential to tube T_4 resets the detector and leaves it in readiness to detect the next short circuit. The sharp exponential rise in potential on the anode of tube T_4 provides the triggering pulse that is fed into the counter stage to indicate the passage of the short circuit. An identical triggering pulse from the anode of tube T_3, indicating the time of initiation of the short circuit, was found to be equally satisfactory for registering the short circuit. Details of the short circuit counter are shown in Figure 3. The instrument is composed of four basic circuits or units: the short circuit detector; two counter stages; and a final counter circuit to register the results on an electromechanical counter. The detector stage is the same as described previously except for the addition of cathode biasing to the thyratrons. Separate biasing resistors are necessary because tube T_4 receives part of its biasing potential from the capacitor C. The detector is followed by the first of two identical counter stages. This is a conventional "scale of two" counting circuit, based on the circuit of Wynn-Williams[3] and is similar to those used in conjunction with Geiger counters. It is a parallel inverter circuit, which consists of the thyratrons T_6 and T_7 and the commutating capacitor C_3 and operates on the general principle described previously. Whenever a positive pulse is impressed on the parallel capacitor-resistor circuits C_4R_G and C_5R_G, a positive current pulse passes through both grid resistors and raises both grids to the firing potential. Whichever tube was not conducting previously is fired and the other tube is extinguished. As often as a positive pulse is received from the detector, the conduction is transferred from one tube to the other. The output of the detector circuit is coupled to the input of the inverter by the triode T_5. This is to prevent the possibility of negative pulses from the detector extinguishing the counting tubes to introduce an error in the count. Positive pulses to the grid of T_5 allow plate current to pass through the resistor R_5 to produce a positive voltage pulse which is fed to the counter inverter. Negative pulses have no effect on the plate current because of the high initial grid bias, and are not transmitted.

Every time the anode potential in tube T_7 goes positive, a positive pulse is transmitted to the second counter stage. Hence, for every second pulse from the detector circuit a positive pulse is transmitted to the second counter stage. The output of the second counter stage produces a pulse for every fourth signal from the detector, and so on. If n counting stages are incorporated, the final stage transmits a pulse for every $2n^{th}$ short circuit. As many counting stages should be used as is necessary to reduce the frequency of the pulses coming from the final stage to a number low enough to be handled by the mechanical counter. Two counter stages were found to be sufficient for the present application. The number of short circuits detected is obviously $2n$ times the reading of the mechanical counter.

The final counter circuit, which is based on the Pickering circuit[8] records the number of pulses from the last counter stage on a Cenco high-impedance counter. Thyratron T_{11} is normally prevented from conducting by the cathode bias maintained by the voltage divider R_{16}

Figure 3. Detailed circuit diagram of the complete short circuit counter



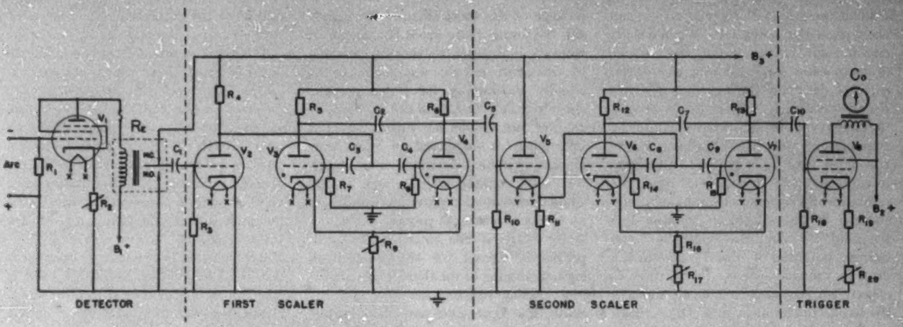


Figure 4. Circuit diagram of the modified short circuit counter

and R_{13}. The positive pulse transmitted from the last counter stage raises the grid of tube T_{11} sufficiently to cause it to conduct and pass current through the Cenco counter, R_{13} and C_{11}. The current surge quickly charges the capacitor to a high value of voltage which simultaneously decreases the tube current and increases the negative value of the voltage on the grid until the discharge through the tube is extinguished. Capacitance C_{11} then discharges through resistance R_{15} until the steady-state bias determined by the ratio between R_{14} and R_{15} is reached, and the counter is reset to record the next impulse. The resistance R_{16} conducts a small polarizing d-c current through the Cenco counter in order to speed its response when an impulse is received.

The circuit components used in the present model of the short circuit counter are as follows: Tubes T_3, T_4, T_6, T_7, T_9, T_{10}, and T_{11} are *type 884* thyratrons. Rectifiers T_1 and T_2 are the two halves of a *117Z6* tube. Tubes T_5 and T_8 are *6P5* triodes. Load resistors R_1 and R_2 are each 7,500 ohms, and load resistors R_6, R_7, R_{10}, and R_{11} are each 10,000 ohms. Commutating capacitor C_1 is 0.025 microfarad. C_3 is 0.05 microfarad, and C_7 is 0.10 microfarad. Coupling capacitors C_2, C_4, C_5, C_6, C_8, C_9, and C_{10}, are all 0.001 microfarad and the grid-leak resistors R_g are all 100,000 ohms. R_3 and R_4 are 3,000-ohm potentiometers, R_8 and R_{12} are 2,000-ohm potentiometers, and R_5 and R_9 are each 100,000-ohm resistances. The counter circuit elements are $R_{13} = 1{,}500$ ohms, $R_{14} = 800{,}000$ ohms, $R_{15} = 500{,}000$ ohms, and $C_{11} = 0.20$ microfarad.

The minimum duration of short circuit that can be detected is determined by the time required for the voltage across the capacitor C to drop from its normal value to a value low enough to allow tube T_4 to conduct. This time delay depends not only on the time constant RC but also on the voltage across C at the initiation of the short circuit. In order to maintain a fixed time delay, R is adjusted before each run to give the required time delay for the average arc voltage to be maintained during the weld. A delay of one millisecond has been adopted for the present. This is obtained by use of a fixed capacitor C of 0.01 microfarad and a resistor R, variable between 50,000 and 100,000 ohms, and calibrated in terms of the average arc voltage. It should be pointed out that the time delay thus determined is constant only to a first approximation because of the random fluctuation of the arc voltage from the average and the random variation in the critical grid voltage of the thyratron. However, this approximation should be reasonably reliable on the average.

The minimum duration of short circuit that can be detected is increased somewhat over the foregoing value because of the commutating time of the capacitor C_1. Owing to the additional cathode bias provided during the switching transient, probably about three time constants, or nearly one-half a millisecond is required before tube T_3 can be reignited after its extinction. If the short circuit is removed before this time interval is concluded, tube T_3 will not be fired until the following short circuit is removed. Since the output pulse of the detector is produced by the voltage rise across T_4 following the firing of tube T_3, any short circuit which is removed too quickly to fire tube T_3 will not be registered. The following short circuit will be detected, however, when tube T_3 is triggered by the removal of that short circuit. This effectively limits the minimum duration of short circuit that is counted to the sum of the time delay introduced by the RC circuit and the commutating time of the detector circuit. An exception would be two or more short circuits intermediate between the two limits in which case alternate short circuits would be detected. The commutating time of the detector also introduces a momentary "dead" period during the interval between the time tube T_3 is fired and the anode potential of tube T_4 is reapplied. Since this interval is shorter than the time delay introduced by the RC circuit to limit the minimum duration of short circuit detected, it does not affect the operation of the circuit. Slightly longer commutating times are allowed for counter stages since requirements for speed of response are reduced in each succeeding stage.

A modified design of the short circuit counter has recently been developed which uses a high-speed magnetic relay for the detector. Details of the circuit used are shown in Figure 4. The relay *RE* is a Stevens-Arnold Company, 6-volt *Model 172* Millisec relay which is designed to operate within one millisecond after it is energized. This speed of response is ideal since the time delay is of the same order of magnitude as the minimum duration of short circuit chosen previously. The coil of the relay is connected in the plate circuit of the pentode V_1, which is controlled by the negative arc voltage fed to the control grid. When the arc is burning, the tube is biased to cut-off and the relay is de-energized. The normally closed contacts allow the capacitor C_1 to charge to line voltage while the grid of the triode V_2 is effectively tied to the cathode by the grid leak resistor R_3. When a short circuit occurs, tube V_1 passes current through the relay which operates to ground the positive plate of the capacitor C_1. This capacitor discharges through R_1 to apply a negative pulse to the grid of V_2 and raise the potential of the plate of tube V_2 suddenly to line value. The sharp pulse from the plate of tube V_2 is fed into the first "scaler," or counter stage, to register the count. When the arc voltage is re-established, the relay is de-energized and the capacitor C_1 is recharged to reset the detector for the next short circuit. The output pulse of the detector is fed into "scaler" circuits which are identical to the two "counter" stages of the original instrument. The final stage which triggers the Cenco counter also was modified in the new design. Experience showed the thyratron circuit used previously to be somewhat critical to adjust and to require occasional readjustment. In the modified form, the Cenco counter is connected in the plate circuit of a *6L6* power amplifier tube V_3 which is normally biased sufficiently to prevent operation of the counter. When an output pulse is received from the final scaler through the coupling capacitor C_{10}, the potential of the control grid of the tube is momentarily raised to allow a surge of current to pass through the counter coil to register the count. The instrument is provided with a voltage regulated power supply to eliminate any instability that might be caused by plate supply disturbances. The complete assembly is housed in a metal chassis mounted on a steel rack which accommodates all the instruments used. The circuit elements used in the modified design are as follows: tube V_1 is a *6AG7* pentode, V_2 is a *6P5* triode, and V_3 is a *6L6* power amplifier; resistances R_1, R_3, R_4, and R_{14} are each 100,000 ohms, and R_2 and R_{20} are variable resistances of 3,000 ohms and 5,000 ohms maximum respectively; capacitance C_1 is 0.005 microfarad and C_{10} is 0.5 microfarad.

Both designs of the Short Circuit Counter have been used in the laboratory. The original design was used over a period of many months and furnished much useful data. The modified design proved to be less critical to adjust, however, and was adopted for general use. The latter instrument is unfortunately limited to studies of short circuits of a fixed minimum duration whose time is determined by the time delay of the relay used. If control over the duration of the short circuits counted should prove desirable, an electronic detector such as used in the original design of Figure 3 would be more flexible.

The Short Circuit Duration Indicator

A mere count of the number of short circuits in the arc includes no measure of their duration. An instrument to measure the average duration of the short circuits, or the proportion of the time the arc is short circuited, is therefore desirable. This need led to the invention of the Arcronograph by Ronay.[4,5] The original purpose for which the Arcronograph was developed was to measure the proportion of the total time that the arc burns. In the usual application, the instrument is used to study the rhythm of the occurrence of the short circuits. The practical design of the Arcronograph does not allow an absolute calibration in terms of the ratio of arcing time to the total time, however, so that the interpretation of the results depends to a large extent on the experience of the operator. To overcome this difficulty, the Short Circuit Duration Indicator shown in Figure 5 was developed for the present investigation. The per cent short circuit time was found to be a more convenient variable to use than the per cent arcing time because of the relatively small short circuit time exhibited by many modern electrodes.

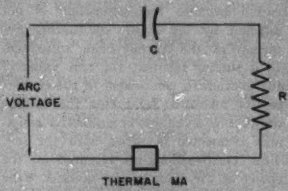

Figure 6. Elementary circuit to measure the standard deviation of a fluctuating direct voltage or current

The circuit is essentially a simple d-c amplifier consisting of the tube T_1 and load resistance R. The arc is connected between the grid and cathode so as to make the grid negative. When the arc is burning, the grid is biased to cut-off and the tube is nonconducting. The occurrence of a short circuit decreases the negative grid potential sufficiently to allow full plate current to flow. This is indicated by full scale deflection on the D'Arsonval milliammeter in the plate circuit. When the arc is short circuited, full scale current will pass through the milliammeter, while no current will pass when the arc is burning. If the frequency of the short circuits is high enough in relation to the inertia of the meter, the milliammeter will indicate the average value of the current. The ratio of the milliammeter reading to the full scale reading is obviously the ratio of the short circuit time to the entire time. If the milliammeter is calibrated in per cent, the instrument can be made direct reading.

Satisfactory operation of the circuit requires that the milliammeter current during a short circuit be absolutely independent of variations in the short circuit voltage caused by the short circuiting metal, and of any change in the plate supply voltage. Since modern tubes cannot be made to saturate, this requirement is insured by the addition of a clipping or by-pass circuit, consisting of the diode T_2 and the polarizing battery E_{bias} connected around the load resistance and milliammeter. As long as the current through the load is less than the predetermined value, the voltage drop across the load is less than the polarizing voltage on the diode, and the diode is nonconducting. When the load current reaches the specified value, the voltage drop exceeds the polarizing potential just enough to make the plate of the

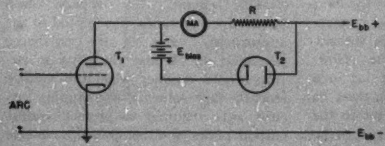

Figure 5 (left). Circuit diagram of short circuit duration indicator

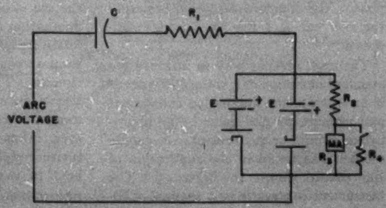
Figure 7 (right). Circuit diagram of the first design of the rms voltage deviation meter



diode positive. Since the clipping circuit has negligible resistance, all current in excess of the specified value is shunted around the load, and the milliammeter current is limited to its full scale value. The values of E_{bias} and R are so chosen that the full scale current is one milliampere. The circuit elements used are as follows: tube T_1 is a *6C5* triode while T_2 is a *6H6* diode. The polarizing potential is provided by a 45-volt "B" battery, so that the resistance R is about 45,000 ohms. The final adjustment of R is made experimentally.

The present model is calibrated to give full scale deflection for 100 per cent short circuit time. The substitution of a multi-range milliammeter with more sensitive scales for the single-range milliammeter now in use would provide an instrument adjustable in range. This would make possible full scale deflection of the instrument with less than 100 per cent short circuit time. Such an increase in sensitivity would be useful for the study of electrodes which have only a relatively small short circuit time. If the full scale reading of the instrument is reduced below 100 per cent, however, care should be exercised to protect the milliammeter from unexpected long period short circuits, such as would occur if the electrode froze to the work. The indicating milliammeter used in the present instrument could easily be replaced by a recording milliammeter to provide a permanent record.

The Rms Voltage Deviation Meter

Turning from a study of the short circuits in the arc stream, valuable information on the stability of the arc can be obtained from a study of the variations in the burning voltage. One of the best mathematical methods of expressing statistical variation about the mean of a number of values of a quantity is the standard deviation. By definition, the standard deviation is the square root of the mean of the squares of the differences between the individual values and the mean value. In the case of a direct voltage or current with a fluctuating component, the standard deviation is simply the rms value of the fluctuating component.

The most obvious way to measure the standard deviation of a voltage or current is to separate the fluctuating component and measure its rms value by an appropriate circuit or instrument. A simple method was found in the application of the circuit shown in Figure 6. The instrument is essentially a thermal milliammeter connected in series with the resistance R and capacitance C across the arc voltage. The capacitor C charges to the average value of the arc voltage; therefore, the algebraic difference between the instantaneous and average values of the arc voltage is impressed across the resistance R. Since the current through the resistance is proportional to the impressed voltage, the current through the milliammeter is directly proportional to the fluctuating component of the voltage. An rms milliammeter can therefore be calibrated directly in terms of the rms value of the fluctuating component of the voltage. A thermal milliammeter is best suited for this application because the calibration is not affected by the highly fluctuating frequency of the current being measured. In a similar manner, the rms value of the fluctuating component of the current can be measured by taking the voltage drop across a suitable noninductive resistance connected in series with the arc. Two considerations are required for the choice of the value of resistance R: the sensitivity of the milliammeter and the range of voltage to be measured. The necessary resistance is obviously the ratio of the expected rms voltage to the full scale meter current. The value of capacitance is determined in turn from the resistance R and the circuit time constant, where the choice of time constant is governed by the length of the time base over which the voltage is to be averaged. Owing to the relative size of the meter resistance, the latter must be included in the total resistance R in the foregoing calculations.

The application of this circuit introduced one practical design problem. When the arc is suddenly short circuited, the voltage drops from the burning voltage of say 20 to 30 volts to less than 5 volts, a drop of 15 to 25 volts or more. Since the capacitor C remains charged to the average value, this difference in voltage is impressed across the resistance R and causes a proportional current through the milliammeter. Owing to the relatively smaller voltage fluctuation during the greater part of the time when the arc is burning, the rms value of the fluctuation over a long period of time is relatively small compared with the momentary peaks which accompany the short circuits. This would result in momentary peak currents through the thermocouple many times the rms value. However, in order to reduce time lag in a thermocouple, the heat storage must be kept to a minimum, and therefore the ratio of maximum allowable current to the rms current is limited accordingly. The choice of a thermocouple meter with sufficient sensitivity to give a reasonable deflection for the range of rms voltage encountered would therefore be severely overloaded by the short circuit peaks and would be burned out. A similar, although more serious, voltage peak will be impressed across the resistance if the arc is suddenly open circuited, and will likewise burn out the meter. The difficulty was overcome by limiting the thermocouple current to a safe value by the addition of a "clipping" circuit similar to that used in the Short Circuit Duration Indicator described previously.

Details of the first Rms Voltage Deviation Meter are shown in Figure 7. The milliammeter was an American Thermo-Electric Company *type 17A* vacuum thermocouple with a 200-microampere D'Arsonval instrument in the output circuit. A heater current of about 4.5 milliamperes was sufficient to cause full scale deflection. A total series resistance R of about 1,000 ohms provided the proper sensitivity for the range of voltage fluctuation usually encountered. The choice of time constant was somewhat flexible. The time constant should be large enough to average the voltage over a period long in relation to the period of fluctuation, yet short enough to allow the capacitor voltage to follow the long time drifts in the average arc voltage. A time constant of the order of 0.1 second was selected for trial and a number of test runs were made under identical test conditions with a number of values of time constant both above and below this value. No appreciable difference was observed in the value of the rms voltage measured over the range of time constant studied. A time constant of about 0.1 second was therefore adopted in the final design. This corresponded to a capacitance of the order of 100 microfarads. This had to be a paper capacitor, because the leakage current through an electrolytic capacitor would have been of the same order of magnitude as the current being measured.

A portion of the circuit resistance, consisting of R_2 of 120 ohms and the heater resistance R_4 of 60 ohms was utilized to determine the current limit set by the clipping circuit. The voltage drop across this resistance was limited to the approximate value of the polarizing potentials E, because the clipping circuits would conduct when the voltage reached this value. Two clipping circuits were required to protect against current peaks of either polarity. Single disk selenium rectifiers were used, with number 6 dry cells for the polarizing potentials to keep the resistance of the clipping circuit to a minimum. The voltage drop in the clipping circuit must be kept low compared with the polarizing potential to produce sharp clipping. The resistance R_1 constituted the remainder of the resistance R. Sensitivity control was obtained by shunting the resistance R_4 across the milliammeter.

The circuit described was used successfully in the laboratory for some time and found to be fundamentally satisfactory. A number of drawbacks were inherent in the design, however, and led to early work on a modified design. Most annoying of the disadvantages was the large value of capacitance required which resulted in an instrument both heavy and bulky. More serious technically, however, was the effective change in time constant introduced by shunting part of the circuit resistance during short circuits. This effect was held to minimum by keeping the ratio of R' to R_1 as small as possible, but could not be eliminated. In spite of these limitations, however, the basic simplicity of the circuit would probably have kept it in use indefinitely had it not been for faulty operation of the clipping circuit which occasionally allowed a thermocouple to be burned out. The use of a cathode-ray oscillograph revealed that although the clipping circuits worked satisfactorily on direct current and 60-cycle alternating current, sudden pulses were passed. A sufficient number of these would eventually burn out the thermocouple. The obvious solution to the problem would be the substitution of vacuum rectifiers, but the higher tube drop would require the use of a higher polarizing potential to produce sharp clipping action. This could be accomplished only by the use of a higher resistance R_2 and a correspondingly smaller resistance R_1. Because of the effect of clipping on the time constant described previously appreciable reduction in the value of R_1' would be undesirable.

The electronic modification of the circuit shown in Figure 8 proved the answer to all the problems encountered before. The basic element of the electronic circuit is still a resistance connected in series with a capacitance across the arc voltage. The voltage drop across a suitably tapped portion of the resistance is measured by a simple bridge-type vacuum tube voltmeter circuit consisting of the two triodes T_1 and T_2 and the two fixed resistances R_1. The input is to the grid of tube T_1 and the output is measured by a thermal milliammeter in series with the resistances R_4 and R_5 between the plates of the two tubes. Since the output current is proportional to the input voltage, the reading of the output meter is proportional to the rms value of the voltage deviation and is calibrated accordingly. A clipping circuit like that described previously is connected across the milliammeter and a suitable portion of resistance R_4. However, sufficient output voltage is available to allow a higher polarizing potential than before. This in turn permits the substitution of vacuum tubes for the selenium rectifiers without seriously decreasing the sharpness of clipping.

The substitution of the vacuum tube circuit for the milliammeter used previously to measure the voltage across R permits the value of R to increase to a value limited only by the maximum allowable grid resistance. A value of 200,000 ohms was satisfactory for the *type 45* tubes used in the design adopted. This permitted the use of relatively small capacitances to obtain the required time constant. Three values of capacitance C_1 of 0.25 microfarad, C_2 of 0.50 microfarad, and C_3 of 1.0 microfarad provide a time constant adjustment to values of 0.5 second, 1.0 second, and 2.0 seconds, respectively. Since the clipping circuit has been removed from R, it no longer has any effect on the circuit time constant. Tube T_2 receives its bias from the adjustable potentiometer R_3. This allows a balance adjustment to be made to compensate for inequalities between the two tubes. A d-c milliammeter (not shown in the diagram) can be connected in place of the thermal meter to provide a more sensitive balance indicator than the thermal meter. The thermocouple is an American Thermo-Electric Company, *type 17A*, vacuum thermocouple, the same as used in the previous instrument. A 200-microampere d-c indicating instrument was first used to measure the thermocouple output. This has since been replaced with a photoelectric potentiometer and recording milliammeter which furnishes a permanent record of the rms voltage deviation. The rectifiers T_3 and T_4 are the two halves of a *117-Z-6* duodiode and the polarizing potentials E are each 7.5-volt batteries. Other circuit constants are: $R_1 = 500$ to 1,000 ohms (variable), $R_3 = 50$ ohms, $R_4 = 2{,}000$ ohms, and $R_5 = 1{,}000$ ohms.

The calibration and clipping characteristics of the circuit with the constants just enumerated are shown in Figure 9

Figure 8. Circuit diagram of the electronic design of the rms voltage deviation meter

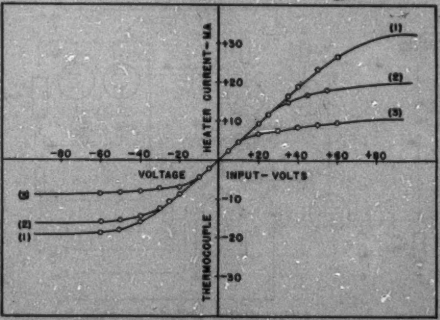
(3) Adjusted for maximum clipping



for three levels of clipping voltage and maximum circuit sensitivity (sensitivity control set on point C). In position 1, the adjustment is set for minimum clipping. The current calibration is essentially linear and independent of polarity over a wide range of voltage fluctuation. Some clipping is introduced in position 2 and still greater clipping in position 3. An intermediate setting between positions 2 and 3 is used generally since it clips at a sufficiently low level to protect the thermocouple, but at a high enough value to provide linear response over the normal range of voltage deviation. Some objection may be raised that the action of the clipping circuit eliminates the greater part of the voltage deviation introduced by the presence of short circuits from the measurement of the rms voltage deviation. This, however, appears to be an advantage as well as a disadvantage since it puts chief emphasis on the voltage deviation when the arc is burning. The inclusion of the short circuits in the measurement of rms voltage deviation would very largely obliterate the deviation introduced by factors other than short circuits. The effects of short circuits are properly studied by the other forms of instrumentation described previously. Precaution should be taken, however, to use the same clipping level for all comparable measurements since a change in the clipping level will modify the value of voltage deviation measured. This requirement not only fixes the position of potentiometer R_4, but effectively limits the setting of the sensitivity adjustment to one position; otherwise a change in the gain of the instrument with a fixed output clipping level would modify the clipping level relative to the input voltage. In practice, therefore, the sensitivity adjustment shown is set for maximum and the sensitivity is controlled by a shunt around the thermocouple.

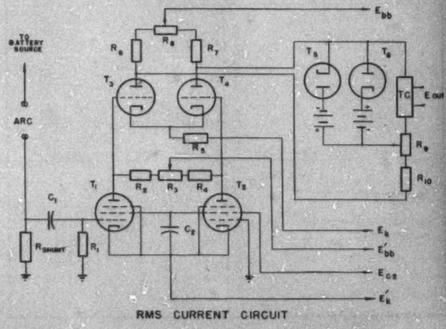
The Rms Current Deviation Meter

The rms value of the current deviation is directly proportional to the rms voltage deviation across a noninductive resistance connected in series with the arc. When a pure resistance ballast is used to limit the arc current, the voltage drop across the resistance is of the same order of magnitude as the arc voltage. An rms deviation meter of identical design to that used for voltage measurements can therefore be used to measure that rms voltage deviation across this resistance. The rms value of the current deviation is computed by dividing the rms voltage deviation by the resistance. This method has proved quite satisfactory in the laboratory where considerable research has been done using a battery source of current with a pure resistance ballast. The substitution of a welding machine for the battery circuit would however prohibit the application of this method. A modified form of the rms deviation meter was therefore designed to measure the voltage deviation across a standard 0.01-ohm oscillograph shunt. This instrument has been designated as the Rms Current Deviation Meter.

Details of the Rms Current Deviation Meter are shown in Figure 10. The circuit used was suggested to the authors by Doctor Warren C. Stoker of the Department of Electrical Engineering of Rensselaer Polytechnic Institute. It is essentially that of the Rms Voltage Deviation Meter with an added amplifier stage to increase the sensitivity. The input voltage from the "shunt" is connected across the series circuit consisting of C_1 and R_1. The deviation voltage, which appears across R_1, is fed directly into the input terminals of the first stage of a balanced d-c amplifier. This amplifier stage is composed of the pentodes T_1 and T_2 and the load resistances R_2, R_3, and R_4. The output from this stage is taken between the plates of the two tubes and fed into the second or output stage cascaded above it. The second stage is almost identical to the circuit of the original Rms Voltage Deviation Meter except that the input is fed to both grids in push-pull. This stage consists of the tubes T_3 and T_4 and the load resistances R_6, R_7, and R_8. The resistance R_5 provides the cathode biasing. The output is taken from the plates of the tubes and measured by a properly protected thermocouple as in the previous instrument. The time constant of the Rms Current Deviation Meter has been retained at 0.1 second making C_1 equal to 0.2 microfarad and R_1 equal to 500,000 ohms. Tubes T_1 and T_2 are *6SJ7* pentodes while tubes T_3 and T_4 are *type 45* triodes. The resistances R_3 and R_4

Figure 10 (below). Circuit diagram of the rms current deviation meter

Figure 11 (right). Instrument assembly used for the study of the d-c welding arc



are each 25,000 ohms and R_6 and R_7 are each 2,500 ohms. The potentiometers R_3 of 100,000 ohms and R_5 of 1,000 ohms are included to provide balance adjustments to compensate for any inequalities in the tubes. An American Thermo-Electric Company, *type 19*, thermocouple with a maximum safe current carrying capacity of 10 milliamperes is used to increase the sensitivity of the instrument. The output can be fed either to an indicating microammeter or to a photoelectric potentiometer and recording milliammeter as in the Rms Voltage Deviation Meter. The latter method is being used currently. The design constants of the clipping circuit are the same as described for the previous circuit. The plate and screen grid potentials are obtained from a voltage divider connected across the output of a voltage regulated power supply.

Applications and Conclusions

The instruments described have evolved over a period of nearly two years of development, trial, and modification. Each is built on an independent steel chassis and provided with its own power supply so that it is readily portable. In the laboratory, the units are mounted one over the other on a steel rack as shown in Figure 11. Two Rms Voltage Deviation Meters are mounted at the top, followed by the Short Circuit Counter, the Rms Current Deviation Meter, and the Short Circuit Duration Indicator, in that order. The photoelectric potentiometers for the Rms Deviation Meters are located out of sight on the bottom shelf of the rack. The recording milliammeters, together with the recording meters for the average arc voltage and current, are shown at the right. The second Rms Voltage Deviation Meter was used originally to measure the rms current deviation before the present Rms Current Deviation Meter was built. It has been retained for the purpose of studying the effect on the rms voltage deviation of changes in such variables as the circuit time constant and the clipping level.

This instrumentation is now being used in the laboratory as an aid to the study of d-c welding arcs over a wide range of arc current and voltage, and for a variety of conditions of electrode coatings. Preliminary results from this investigation have been published previously.[1,6] They indicate that there are pronounced trends in the rms voltage and current deviations and the number of short circuits as the arc voltage and current are varied. These trends have been found to be different for different types of electrodes and even for different brands of electrodes of the same class. A marked contrast has been observed between the consistency of results with uniformly dried electrodes and electrodes taken directly from the package. These results indicate that the instrumentation is capable of distinguishing between different types of electrodes and different test conditions. Final evaluation of these instruments for arc studies must await the outcome of more extensive tests now being conducted in the laboratory. The results of this investigation may show one or more of these instruments to be superior to the others and lead to their adoption for future work. On the other hand, experience may suggest that some modifications in the present instrumentation would be desirable, or that further instrumentation should be sought.

Transformer Manholes and Vaults: Design and Ventilation

L. F. PORTER
ASSOCIATE AIEE

DEMAND for electric power within urban areas, increasing at a rate greater than population growth, poses a problem of major magnitude to the public utilities whose obligation it is to supply that power with a maximum degree of safety, reliability, and economy to the public. This power demand falls within two classifications: domestic and small commercial or industrial users, whose individual demands do not exceed 100–200 kva each and may therefore be considered to constitute a generally distributed load without substantial concentrations; and the larger commercial and industrial users who individually require substantial blocks of power and sometimes present major problems of supply to the power company. The load growth in the latter classification stems from three sources:

1. New buildings whose design includes adequate space provision for the anticipated power requirements.
2. Older buildings whose demand is growing substantially beyond that originally contemplated because of the introduction of air conditioning, considerably increased lighting intensity, or change in the use of the building such as conversion from a warehouse to a loft building with increased lighting and miscellaneous power requirements.
3. Buildings that have been supplied by private plants which the owners have decided to discontinue in favor of purchased power.

Single buildings in the last classification have presented the problem of supplying new blocks of power in the order of 5,000 kva from the public utility's secondary network system and have required the construction of multibank transformer installations at two or more points.

This paper is concerned with the basic elements in the design and ventilation of transformer manholes and transformer vaults required to supply secondary network load. It is confined to network systems for simplicity, but structures for underground radial systems would be fundamentally the same with some modifications for different equipment.

General

Secondary network systems serving a distributed load without substantial concentrations of power generally are supplied from individual transformer installations strategically located for maximum economy in distribution. Such single-transformer installations are commonly located in the roadway where they may be subject to flooding; hence submersible equipment is used. Congestion of structures under city streets has led to the design of highly specialized top-connected transformer-network protector units which may be installed in minimum sized manholes. These manhole units are connected to the network secondary mains and usually have no customer service connection.

On the other hand, where substantial concentrations of load occur, say in the order of 200 kva or more, transformer installations adjacent to the customer's point of service connection are indicated. These transformers are generally located under the sidewalk or inside the building adjacent to the property line and either at the first basement level or at grade. Nonsubmersible vault-type equipment may be used as there usually is little danger of flooding through sidewalk gratings. These vault installations provide for a customer's service connection and have a secondary tie to the street network. Multiple installations of transformer manholes in the roadway are not practicable because of subsurface congestion by other structures and the difficulty of interconnecting secondary cables.

The number of banks required will be determined by the customer's maximum demand, the size of transformers used, the design of the secondary network system and the permissible loading of the transformers under emergency conditions.

Factors Affecting Design

The design for a specific installation is affected, and sometimes is governed, by conditions peculiar to the particular project such as are indicated below.

Space Available. This, particularly for multiple bank installations to be installed for existing buildings, often presents a problem of major difficulty. It frequently may tax the ingenuity of the designer to fit the necessary equipment into the space which can be obtained within reasonable distance of the customer's switchboard, and, at the same time, to obtain the area of grating or louvered panels essential for reliable cooling by natural ventilation. Since space is not generally available at grade for network transformer installations, only subgrade structures are contemplated here.

Type of Equipment Available. Dry-type transformers, for instance, with class *B* insulation may be considered ideal from the safety angle but require more space than liquid filled units, operate at a higher noise level which may be objectionable for certain installations, must be protected from rain unless submersible designs are used, and are not presently available at primary voltages above 15 kv.

City Codes and Regulations. These may impose restrictions as to location and

L. F. PORTER is an Assistant Engineer with the Consolidated Edison Company of New York, Incorporated, New York, N. Y.

dimensions of gratings which are required for ventilation and access, and thus directly affect the design and location of structures under the roadway or under the sidewalk.

Climate. Utilities, operating in areas with summer temperatures averaging above 30 degrees centigrade over a 24-hour period and having peak loads in summer, will require correspondingly larger ventilation gratings for transformer installations.

Nature of Load. A load cycle characterized by a peak demand of substantially over eight hours' duration—the maximum usually encountered on a network system—may require that the transformers be furnished with more ventilation than would be supplied otherwise.

Soil Conditions. Solid rock, or poor soil which would necessitate pile foundations, may make it advisable to seek space within the customer's building.

Design

A description of the basic features desired in the design of transformer manholes and vaults is offered as a means for measuring the adequacy of designs contemplated for specific instances. Adequately designed transformer manholes and vaults will provide:

1. Ventilation adequate for optimum utilization of the transformers and network protectors.

2. Direct and immediate access for maintenance crews 24 hours a day, preferably through street or sidewalk gratings.

3. Arrangement of transformers and associated equipment to provide approximately equal division of load among the transformers where two or more banks are paralleled on the same service bus.

4. Isolation of equipment to the extent of confining any fire or explosion, which may occur, to the vault in which the trouble originates so that the balance of the installation will operate unimpaired and the service will not be interrupted.

5. Isolation of service cables from transformer vaults and isolation of the cables associated with one transformer bank from other transformers.

6. Minimum size manhole or vault compatible with installation and with maintenance which includes: rolling out the network protector switch for maintenance and repair, repair of transformer terminals, sampling transformer fluid, removing debris which accumulates between the transformer and compartment walls, and replacing cables in case of failure. It is obvious that the design of equipment used is a major factor in determining space required; for instance, in the case of dry-type transformers, a minimum 12-inch separation between compartment walls and transformer is required to assure adequate air circulation, and, also, it is apparent from the construction of this type of equipment that space must be allowed to permit removing the transformer housing panels for cleaning purposes.

7. Adequate drainage, which is particularly important where nonsubmersible equipment is used, to avoid damage to equipment and possible loss of service.

Ventilation

Transformers may be loaded continuously to their full nominal rating only when the cooling air at no time exceeds 40 degrees centigrade and the average temperature of the cooling air during any 24-hour period does not exceed 30 degrees centigrade. Most of the heat released in the manhole or vault must be removed by ventilation, as only a minor part of the heat is dissipated through the walls. Heat loss through walls may be quite negligible where the transformers, in a multiple-bank installation, are on both sides of partition walls, and the vaults are located adjacent to a boiler room or steam mains.

Natural ventilation is essential for a maximum degree of dependability, for there are no thermostats, switches, wiring, motors or valves to get out of order and there is no failure of this type of equipment during peak load with consequent high transformer temperatures. Gratings in the sidewalk or roadway, or louvered openings in an outside building wall, afford the most reliable ventilation for subsurface vaults. It is essential that the transformers be close to these openings, both horizontally and vertically, for best results.

Ventilation ducts with horizontal offsets may be generally ineffective. Where vertical vent shafts are used for deeper vaults, separate inlet and outlet openings, properly located, may improve ventilation. Larger net vent opening may be required to offset the shaft resistance to air flow.

The effectiveness of the ventilation for a given vault does not lend itself readily to accurate determination because of the interrelation between vault dimensions, grating location, and the position of the transformer. Exposure to the sun also is believed to have an appreciable effect. Obviously, a full roof grating would permit a maximum transformer loading, but this is not generally obtainable in the sidewalk because of restrictions such as limited grating widths and prohibition of gratings in front of doors or under windows established by the city authorities, and customers' objections.

A minimum acceptable ventilation area must be established to avoid limiting unduly the loadability of the transformer installation.

The National Electrical Code minimum requirement of two square feet net vent area per 100 kva installed transformer capacity appears to provide adequate ventilation in most instances for cyclic loading where the 24-hour average ambient temperature does not exceed 30 degrees centigrade. On this basis, 500- and 1,000-kva installations (with total transformer and network protector losses of approximately 7 kw and 12.5 kw respectively at 100 per cent load) would be provided 10 square feet and 20 square feet net vent area respectively. Tests indicate that vaults or manholes, designed compactly and with transformers near or under the gratings and provided with 10 square feet or 20 square feet net vent openings, have heating constants, respectively, of approximately 4.0 and 2.5 degrees centigrade rise of vault air, above outside ambient temperature, per kilowatt loss. This "vault heating constant" is of direct value in computing the permissible loading of a transformer installation as recommended in ASA Standard C57.32.[1]

Vaults with heating constants of 4.0 and 2.5, equipped with 500- and 1,000-kva units respectively, will permit normal loading on standard network transformers in the order of 100 per cent of rating when operating on a typical industrial power cycle with a load factor of 60 per cent and an 8-hour peak load, and an average 24-hour ambient air temperature of 26 degrees centigrade. Since a network transformer cannot normally carry full load without being severely overloaded when adjacent banks are out of service, the critical condition for which the permissible loading of the transformer must be computed is the contingency of one or two adjacent banks out of service, depending upon the basis upon which the system is designed to operate. The frequency with which this emergency operation is expected to occur will guide the utility engineer in determining the maximum permissible copper hot-spot temperature, with its attendant sacrifice of life of the equipment, which should be tolerated.

Where the 24-hour average ambient temperature is above 30 degrees centigrade, auxiliary means of heat removal, such as a blower or water cooling, may be required. In every case, the use of the largest grating permissible is essential for maximum dependability of operation.

Ventilation should be provided for all subsurface vaults which do not contain transformers or network protectors and where moisture may accumulate, to check corrosion. Experience has shown that, where such subsidewalk vaults have the sidewalk access opening covered with checker plate instead of grating, steel and copper within the compartment have suffered severe corrosion.

Ventilation Ratio

Electrical failure within a liquid-filled transformer sometimes generates sufficient pressure to rupture the tank or blow off the cover with considerable force. If the transformer fluid is of the noninflammable type, this initial or "primary" explosion may be followed by nothing more than the generation of a highly noxious gas and black smoke in great volume. However, in the case of a primary explosion rupturing the tank of an oil-filled transformer, an oil fire may follow or, in some instances, a much more violent "secondary" explosion may occur. This secondary explosion results from the entire vault having been filled with an explosive gas generated by the action of an electric arc on the transformer oil.

It also may be noted at this point that a similar explosion sometimes follows a fault on cables in a poorly ventilated vault which has been filled with an explosive mixture generated by the distillation of insulation. Provision of limiter or fuse protection for cables will greatly reduce, but cannot entirely eliminate this hazard.

Although a secondary explosion following the failure of an oil-filled transformer is uncommon and although the similar "space" explosion following a cable failure is also unusual, either explosion may be highly destructive if the vault in which it occurs is not built sufficiently strong to protect from damage any equipment or personnel which may be near the wall of the vault when the explosion occurs. It is important, therefore, that walls be built sufficiently strong to contain such an explosion.

The amount of gas which can accumulate in a vault will be kept at a minimum by using the smallest size vault practicable, and by providing a maximum of ventilation to reduce the rate of gas accumulation. The smaller this ratio of vault volume to net vent area, the less will be the pressure developed within the vault should an explosion occur and hence the lighter will be the construction necessary to withstand the explosive force.

Data concerning the maximum pressures produced by the explosion of transformer-oil vapor or insulation-produced vapor mixtures are not available. However, data obtained from investigations of dust explosions in vented enclosures, when studied and correlated with data concerning the gaseous products of electric-arc-decomposed transformer oil, offer a rational basis for approximating the probable maximum forces that might result from an explosion within a transformer vault. Such a study has been made and is described in Appendix I. Briefly, these data indicate that the violence of an explosion of the gaseous products of electric-arc-decomposed transformer oil may be in the order of four times as great as that of alkali starch dust, which will produce one of the most violent dust explosions. Curve *A*, Figure 1, obtained from data published by Brown and Hansen of the Bureau of Chemistry and Soils,[10] shows how the pressure developed by alkali-dust explosion in a vented space will vary with the volume of the space per square foot of vent area. Curve *B*, Figure 1, showing the estimated maximum pressure which may be developed by a secondary explosion in a transformer vault, is obtained from Curve *A* by multiplying each ordinate by four. Curve *B* is therefore hypothetical, but there is strong evidence that it is of the right order of magnitude. It is offered tentatively as a basis of design in the absence of more accurate information.

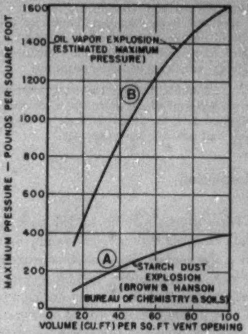

Figure 1. Approximate explosion pressures developed in vented enclosures

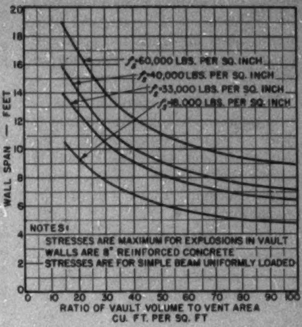

Figure 2. Stresses developed in vault walls by explosion of oil vapor

This curve is applicable where ventilation is so distributed that each unit of volume is afforded its share of vent opening. Thus, an explosion in a long narrow vault, with vent opening only at one end, might develop a substantially higher pressure than is indicated by the curve.

Figure 2 shows curves of constant stress in an 8-inch reinforced concrete wall, resulting from the explosion of an oil-vapor mixture within the vault, for various wall spans and volume–vent or ventilation ratios.

Construction

Transformer manholes and transformer vaults, to be built in unexcavated subsurface space, are best constructed of reinforced concrete for strength and water-tightness. Reinforced concrete is required for strength where explosion-proof vaults are to be built.

Vaults housing oil-filled transformers should be sufficiently strong to withstand an explosion, to the extent of protecting from damage or injury any property or persons that might be occupying space adjacent to the vault walls should an explosion occur within the vault. Explosion-proof construction also should be provided for all vaults containing cable, particularly where no short-circuit protection is provided and where ventilation is poor, for destructive explosions sometimes follow the distillation of cable insulation by short-circuit currents.

Askarel transformers should be housed in separate compartments and so ventilated that, should a failure rupture the transformer tank, the highly noxious fumes which may be generated in great volume, will not seep into the customers premises or deny access to adjacent vaults by operating personnel. Construction should be sufficiently sturdy to hold within the compartment any part of the transformer which may be thrown off by force when the tank is ruptured.

Experience also has shown that oil-filled potheads may explode violently upon failure.

Dry-type transformers with type *B* insulation, on the other hand, appear to offer a minimum of hazard to property in their immediate vicinity, but experience to date has been too limited to indicate whether, under fault conditions, explosive gases may be generated in sufficient volume to produce an explosive mixture within a vault. Vault-type units however, must be protected from the weather and the air must be reasonably free of dust if frequent cleaning is to be avoided.

Precast Concrete

Precast construction is particularly suitable and economical for transformer manholes wherever soil is sufficiently firm for that type of construction and wherever the space is not too congested by other subsurface structures. An equal or perhaps more important factor in favor of precast construction, in areas of heavy traffic, is the material reduction in the time the street is obstructed for construction. Transformer vaults also may be precast, but their use may be restricted by limitations in size and weight which can be transported, for vault-type equipment requires more space than the submersible top-connected equipment usually installed in manholes. Also, the inflexibility of precast designs sometimes will make field-poured construction necessary to use the limited space which may be available.

Roof and Gratings

The strength of the sidewalk or roadway roof slab and ventilation grating necessary for traffic is generally set by city code. Where vaults are located under the sidewalk adjacent to the curb, it is advisable to provide sufficient strength to sustain the wheel load of trucks that occasionally mount the curb. Where vaults are to be installed under driveways, roadway construction must be provided.

Sidewalk gratings which meet all these described loading conditions are commercially available which provide net ventilation openings of 63 to 70 per cent of the gross area, depending on weight of construction.

Providing a hinged exit and a permanently installed ladder will facilitate access for maintenance crews. In the case of street manholes, however, the hinged exit is hardly justified, as safety requires that a barricade be erected and a man be stationed at the open grating. Manhole gratings which have been made

in sections of two feet by five feet can be opened readily by two men.

Drainage

Where submersible equipment is used, drainage is desirable to reduce the cost of maintenance, if it can be obtained at moderate cost. Vault-type equipment, particularly the nonenclosed network protector, must be protected from flooding at all times. Frequently the impracticability of obtaining a gravity drain will force the use of a permanently-installed automatic sump pump. Where the probability of flooding the vault is very remote, a nonsubmersible motor, protected by a diving bell, may be used, but a sump pump which is apt to operate frequently should be provided with a submersible motor to avoid the overheating that may be caused by a diving bell.

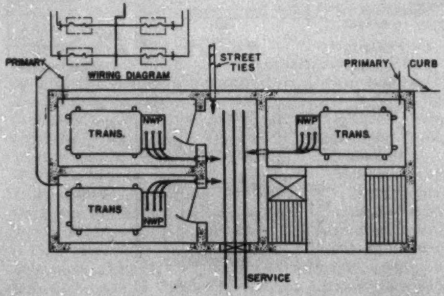

Figure 8. Vaults adjacent to curb

Network protector attached to end of transformer, scheme *A*

Conduits

Secondary conduits interconnecting transformer vaults are preferably of nonmagnetic material, such as Transite or concrete, to obtain a minimum impedance. This is particularly important where several transformers serving the same customer's switch are located at different distances, in order to obtain the best possible division of load. Conduits laid under floors in such a manner that water can be trapped, should be avoided where practicable. Where ducts are so installed, lead-covered cables should be used to protect the cable insulation from water absorption.

Design Illustrations

As an aid to clarifying and visualizing the design features described previously, several illustrative sketches have been prepared which include clearance dimensions that are the minimum considered acceptable with liquid-filled transformers to permit installation, maintenance, and repair of secondary cable terminals.

Figure 3 shows a transformer manhole installation. The transformer manhole offers the simplest design problem since it is installed as an isolated unit directly connected to the network mains and has no provision for a service connection.

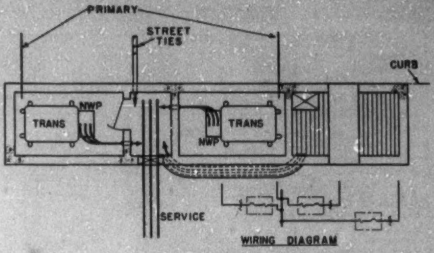

Figure 8(A). Vaults adjacent to curb

Network protector attached to end of transformer, scheme *B*

This illustration shows a combination-type unit, top-connected, installed in a transformer manhole which allows little space about the unit except at the network protector end, where a 3-foot space is provided for network protector maintenance. A full roof grating, made in 2-foot sections which can be handled by two men, provides a maximum of ventilation and accessibility. A drainage sump assists in maintaining a dry floor.

Figures 4, 5, and 6 show layouts for 3-bank vault installations with separately-mounted network protectors, located under the sidewalk at the building line, under the sidewalk with the network protectors inside the building at basement level, and entirely inside the building at basement level with sidewalk ventilation, respectively. A separately-mounted network protector affords a maximum of flexibility in the arrangement of equipment; this is sometimes of great importance where the available

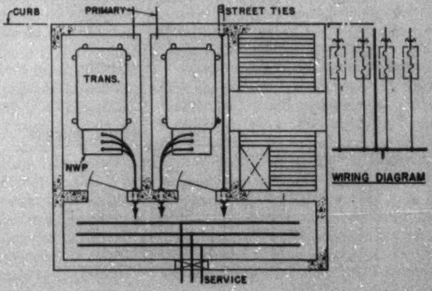

Figure 8(B). Vaults adjacent to curb

Network protector attached to end of transformer, scheme *C* space is very limited. Obviously, however, some space and labor of installation might be saved by mounting the network protector on the side of the transformer, as is shown in Figure 7. The network protector may be mounted on the end of the transformer and the compartments arranged as indicated in Figures 8, 8(A), and 8(B), but complications may arise in obtaining gratings where required, or the long vault construction may make it difficult to obtain the necessary space.

It will be noted in these figures that bus bars are indicated for service connections. This is a desirable feature to limit the number of cables which are connected to the bus. Also, a network protector is located under the service bus—a construction which is economical in the case of a separately-mounted network protector. This network protector is not considered a hazard to service continuity provided the bus is adequately supported with fire-resistant materials.

Appendix I

Published Data—Dust Explosions

The subject of dust explosions has received considerable study by the United States Department of Agriculture,[6,7,10] the United States Bureau of Mines,[8] and the Factory Mutual Laboratories.[9]

The United States Department of Agriculture published the results of tests on 133 materials for which they list a maximum pressure, average rate of pressure rise, and maximum rate of pressure rise for two concentrations of each dust used.[7]

It is stated in this article that the maximum pressure, maximum rate of pressure rise, and average rate of pressure rise are prime factors in determining the severity of an explosion. It is noted from the data that in comparing alkali starch, one of the most explosive dusts, with yellow corn meal, the ratio of the average of these factors is the same as that of their flame propagation rates. Results of tests on vented dust explosions, reported by Brown and Hansen of the Bureau of Chemistry and Soils,[10] show the relation between maximum pressure developed and vent area per unit volume of the test cubicle. Curve *A* of Figure 1 was obtained from these data. These investigators stressed that the shape of the compartment is important and that where the space is not a cube, the vent area should be distributed so that each unit of volume has its proportionate share of vent area.

Explosion of Gaseous Products of Electric-Arc-Decomposed Oil

A correlation between alkali starch explosions and an explosion of the gaseous products of electric-arc-decomposed transformer oil would provide a means for approximating pressures which might develop in a transformer-vault explosion. One investigator states that, although explosive pressures of inflammable dusts may exceed those obtained from vapors of gasoline, acetylene, or hydrogen, the rate of flame propagation for a mixture of dust and air is slow compared with that for vapor explosions.[9]

Table I shows the approximate gas constituents of arc-decomposed oil, explosive limits in air, the maximum rate of flame propagation of each constituent, and the calculated rate of flame propagation in starch dust. The rate of flame propagation for the entire mixture of gaseous products is not known, but these data indicate it is probably at least 300 centimeters per second, or something over four times the rate for starch dust. Additional evidence of the rapid rate of pressure rise resulting from an oil and gas explosion is shown by W. Dann.[11] Although the scale of his curve is too small for accurate reading, it appears that the time required to reach maximum pressure is in the order of 0.02 to 0.03 second, as compared to 0.096 second for alkali starch.

It thus appears that the rate of flame propagation in an oil and gas mixture is approximately four times that of starch dust, and that the severity of the explosion will be about in that proportion. Using this ratio as a basis for correlation with alkali starch explosion, it is possible to arrive at a relation between maximum pressure and vent area for an oil and gas explosion.

The Temperature Rise of Cables in a Duct Bank

J. H. NEHER
MEMBER AIEE

IN THE calculation of the temperatures attained by underground cable systems installed in duct banks, it has been customary to base such calculations upon a set of experimentally determined thermal resistances commonly known as the "National Electric Light Association Duct Heating Constants" by which the temperature rise above ambient earth of cables located in the duct bank may be calculated under stated conditions of duct occupancy.

While this procedure has been satisfactory generally, there has been an increasing need for a fundamental method by which the temperature rise at the surface of the cables could be calculated in terms of the heat loss of the cable-in-duct system, its geometry, and the thermal resistivity of the earth. This would permit the clarification of certain ambiguities now attendant in the duct-constant method, and also would permit a direct comparison of the relative thermal efficiencies of the pipe-type and cable-in-duct transmission systems.

Methods of thus calculating the temperature rise of cables in duct are not new. A number of such methods have appeared in literature. These range from the fundamentally theoretical method discussed by Bailey,[1] to the quasi-empirical methods of Kirke[2] and Bauer.[3] Nevertheless, these methods have not found general favor among cable engineers, possibly because the basic theory is not understood thoroughly, or because of a natural hesitancy to use empirical methods based on someone else's power system.

This paper will discuss the fundamental theory applicable to a direct calculation of cable temperatures from the basic geometry and physical properties involved, and also such factual data as is available in support of the theory.

General Considerations

In a previous paper the author has discussed the solution for the temperature rise of a cylindrical radiator,[4] such as the pipe of a pipe-type cable system, buried in the earth, under conditions where the surface of the radiator is for all practical purposes an isothermal. Considering the simplest of cable-in-duct installations—a single cable in a single duct—the cable surface is an isothermal, but, strictly speaking, neither the duct wall nor the duct periphery are isothermals because the cable is not centered in the duct and because all points in the rectangular duct periphery are not equidistant from the cylindrical source of heat flow. In the case of a multicable-in-duct structure, the situation is further complicated by the usual dissymmetry of the cable positions and the interaction of the heat flow from the various cables.

A theoretical solution of this problem which is sufficiently simplified to be practical must involve the assumptions that the duct walls and duct periphery may be treated as cylindrical isothermal surfaces. Cable engineers are generally agreed on this point. The main points of diverging opinion concern the determination of the thermal resistance between cable and duct wall, and the formulation of the equivalent radius of an isothermal cylinder representative of a group of loaded ducts which properly accounts for the interacting heat flows from these ducts.

Of less importance is the matter of determining the equivalent radius of the duct structure, since this radius must appear in the calculations if differing thermal resistivities of the duct structure and earth are to be used.

If these values can be established, however, it follows from the Kennelly formula for the temperature rise of a buried cylindrical radiator,[4] that the temperature rise at the surface of a centrally-located cable in a duct can be given by the expression

$$\Delta T_s = Q_c H_{sd} + 0.012 Q_d' \times \left[\rho_d \log_{10} \frac{2L}{R_d} + (\rho_e - \rho_d) \log_{10} \frac{2L}{R_b}\right] \text{ degrees centigrade} \quad (1)$$

in which

Q_c = heat flow from given cable in watts per foot
Q_d' = effective total heat flow from all of the cables in the duct bank (including loss factor)
H_{sd} = thermal resistance between cable sheath and duct wall in degree centigrade feet per watt
ρ_d = thermal resistivity of the duct structure in degree centigrade centimeters per watt
ρ_e = thermal resistivity of the earth in degree centigrade centimeters per watt
R_d = equivalent radius of the group of loaded duct walls
R_b = equivalent radius of the duct bank
L = distance from center of duct bank to surface of earth

The use of the long form of the Kennelly formula in the development of equation 1 is not justified in view of the approximate nature of R_d and R_b.

Equation 1 assumes a uniform resistivity throughout the earth and neglects surface effects which may be included if desired.[4] If the duct structure is located beneath street paving of thermal resistivity ρ_p its effect may be cared for by the addition of another term within the

The author wishes gratefully to acknowledge the help of G. B. Shanklin of the General Electric Company in establishing the average geometry involved in the tests from which the National Electric Light Association Duct Heating Constants were formulated; and the kindness of the Johns-Manville Company in furnishing their test data on fibre and Transite ducts.

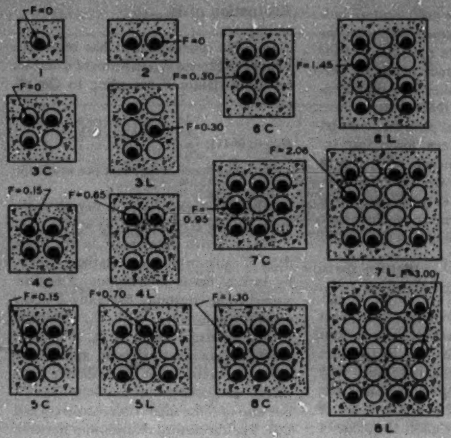

Figure 1. Typical duct bank configurations

brackets of equation 1, for which it is sufficiently accurate to use

$$(\rho_p-\rho_s)\log_{10}\frac{L}{L-p} \text{ degree centigrade centimeters per watt} \quad (2)$$

in which p is the thickness of the pavement.

As a practical matter, however, ρ_d, ρ_e, and ρ_p are of the same general magnitude, and since they will vary among themselves seasonally with the moisture content in a manner which cannot be predicted with any degree of accuracy, it often is sufficient to assume that they will have the same effective value ρ'. This matter is discussed in reference 4, together with methods of determining this effective value.

On this basis, equation 1 may be simplified to

$$\Delta T_s=Q_cH_{sd}+0.012\rho'Q_d'\log_{10}\frac{2L}{R_d} \text{ degrees centigrade} \quad (3)$$

Our problem, therefore, consists in the evaluation of H_{sd}, R_d, and R_b.

Evaluation of R_d

There appears to be a general feeling among cable engineers that, because of the complicated heat-flow pattern which exists in the immediate vicinity of the ducts of a multicable-in-duct installation, the value of R_d for use in equations 1 or 3 cannot be derived on a reasonably simple theoretical basis. As a result there is a tendency to accept the so-called "equal periphery" method as a simple and satisfactory means of evaluating R_d. In this method R_d is taken to be the radius of a circle whose perimeter is equal to the periphery of a boundary line drawn around, and tangent to, the inner walls of the loaded ducts.

It must be realized, however, that R_d and equation 1 or 3 are merely means to an end—the calculation of the temperature rise of a particular duct wall, assumed to be isothermal, which is operating in the vicinity of other loaded ducts. Looked at from this point of view, the value of ΔT_d may be determined graphically by plotting the lines of heat flow, as done by the British[5] and discussed by Bailey,[1] or, much more simply, by the application of the principle of superposition.[1,4] This procedure, outlined in Appendix I, results in an expression of the form

$$\Delta T_{d1}=0.012\rho \quad Q_1\log_{10}\frac{2L_1}{r_d}+ Q_2\log_{10}\frac{L_1+L_2}{d_{12}}+\ldots.+ Q_n\log_{10}\frac{L_1+L_n}{d_{1n}}\Bigg] \text{ degrees centigrade} \quad (4)$$

in which the numerical subscripts refer to arbitrary numbers assigned the individual loaded ducts in the bank, number 1 being the reference duct for which the temperature rise is desired. Thus, d_{12} is the center-to-center distance between the reference duct at depth L_1 and number 2 duct at depth L_2, and r_d is the duct wall radius. The temperature rise thus obtained is above earth ambient temperature at the depth L_1.

By the use of an ingenious electrical analogy consisting of a model test setup in which the thermal quantities are replaced by their corresponding electrical counterparts,[1] Bailey has demonstrated the correctness of equation 4 for the case of six isothermal duct walls buried in a uniform medium. Equation 4 does not take account of any empty ducts which may be present and which, having an effective thermal resistivity considerably higher than the duct structure itself, may be presumed to have some effect on the result. The magnitude of this effect may be obtained readily with the electrical counterpart equipment, but, unfortunately, this was not covered by Bailey. It is probable that the effect is minor and that its omission will not introduce any greater errors than some of the other assumptions which have been introduced.

In the majority of cable-in-duct calculations, the cables all dissipate the same amount of heat, or so nearly so that the values of Q in equation 4 may be taken as being equal to Q_d'/N, where N is the number of loaded ducts. Under these conditions equation 4 becomes

$$\Delta T_{d1}=0.012\rho\left[Q_d'\log_{10}\times\frac{L_1\sqrt[N]{2(1+L_2/L_1)(1+L_3/L_1)\ \ldots}}{\sqrt[N]{r_d\times d_{12}\times d_{13}\ldots}}\right] \text{ degrees centigrade} \quad (5)$$

Equation 5 results in a slightly different value for each loaded duct. If we consider a centrally-located loaded duct of depth L, equation 5 becomes substantially equal to

$$\Delta T_d=0.012\rho Q_d'\log_{10}\frac{2L}{\sqrt[N]{r_d\times d_{13}+d_{13}\ldots}} \text{ degrees centigrade} \quad (5a)$$

Hence, by comparison with the second term of equations 1 or 3

$$Rd=\sqrt[N]{r_d\times d_{12}\times d_{13}\ldots} \quad (6)$$

The procedure outlined is obviously suitable for determining the temperature rise of any point in the duct structure and thus the temperature rise of the air in any unoccupied or idle duct. The corresponding expression for R_i, the equivalent radius of an idle duct, is

$$R_i=\sqrt[N]{d_{12}\times d_{13}\times d_{14}\ldots} \quad (7)$$

Figure 1 shows a number of typical duct bank configurations with from one to eight loaded ducts. In Figure 1, C indicates close grouping and L indicates loose grouping. A determination of the degree of accuracy entailed in equation 5a as applied to these configurations, with consideration for possible effects of the empty ducts, could be readily made by means of the electrical counterpart equipment with insulating media inserted to represent the empty ducts. The procedure of Bailey[1] could be materially simplified by the use of a thin sheet or coated surface of uniform electrical-resistivity material instead of the water bath which he employed.

Any appreciable effect of the unoccupied ducts thus could be reduced to correction factors applicable to equations 6 and 7. Such a project would be of great value, and it is hoped that means may be found for undertaking it.

For comparative purposes, Table I has been prepared for the configurations of Figure 1, assuming the values for r_d, d and L therein stated. Values of the $\log_{10}$ ratio also are given. If a value of $\rho' = 83$ degree centigrade centimeters per watt be assumed, these values of the $\log_{10}$ ratio are equal to the thermal resistances involved, in degree centigrade feet per watt. It will be noted that the thermal resistance between a loaded duct wall and a centrally-located inside idle duct is inappreciable in respect to the total thermal resistance from loaded duct wall to ambient. This is merely a theoretical justification of a fact which may be deduced from a consideration of the heat flow paths involved, and, thus the temperature rise of an inside idle duct is justifiably employed as a bench mark by which the performance of a given duct bank readily may be determined.[6]

Two other significant points are indicated by Table I. The thermal resistance between the occupied ducts and an outside idle duct is too variable to permit the use of the temperature rise of an outside idle duct as a bench mark unless the particular geometry is taken into consideration. Also, over-all thermal resistances calculated by the equal periphery method average about 10 per cent lower than by the superposition principle, and slightly but not appreciably lower than the over-all thermal resistances of outside idle ducts. From this we must conclude that the equal periphery method is not a valid means of evaluating R_d.

Evaluation of R_b

As indicated previously, the exact evaluation of R_b is relatively unimportant since the thermal resistivity of the duct structure and the surrounding earth may be presumed to be so nearly the same that a considerable variation in the value of R_b will not appreciably affect the value of equation 1.

Equation 6 for the evaluation of R_d will be recognized as the equation for the "geometric mean radius" of a group of cylindrical conductors as commonly used in overhead transmission line calculations. For consistency, therefore, it would be logical to employ for R_b the corresponding expression for the geometric mean radius of a rectangle. This is equivalent to the geometric mean distance of a rectangle from its center, the expression for which, as given by Dwight,[7] is

$$R_b = 0.112 P_b \tag{8}$$

in which P_b is the periphery of the rectangular duct structure.

R_{io} = equivalent radius of centrally located outside empty duct, by equation 7

R_d' = equivalent radius of occupied ducts, by equal periphery method

L = depth of center of duct bank below earth's surface

Evaluation of H_{sd}

In cable calculations it has been customary to express H_{sd} in terms of a surface resistivity factor β according to the expression

$$H_{sd} = 0.00411 \frac{\beta}{D_s}$$

degree centigrade feet per watt (9)

in which β is expressed in degree centigrade square centimeters per watt.

This practice dates back to the early days of cable-in-duct calculations,[8] when, for lack of better information, β was assumed to be constant. Actually β is not constant and varies with D_s, although, within the usual range of D_s, β may be taken as constant without appreciable error. As indicated in Appendix II, H_{sd} is theoretically dependent not only upon D_s but also in some slight degree upon Q and D_d. The theoretical relationship between H_{sd} and D_s for average values of $Q = 10$ watts per foot and $D_d = 4$ inches is expressed in the form of a curve in Figure 2.

Because of the departure of the duct wall from an isothermal cylinder on which Appendix II is based, the theoretically-derived H_{sd} must be correlated with such test data as are available.

In a thesis written in 1925, Barenscher[9] gives the results of temperature measurements made at three points—top, bottom, and side—on a cable sheath and the corresponding three points on the inside of an enclosing fibre duct encased in a concrete envelope. These results, based on the average sheath and inner-duct-wall temperatures for $Q = 10$ watts, are given in Table II and are spotted on Figure 2. There obviously was something wrong with the $D_s = 2.13$ test, but otherwise the points fall on a curve parallel to the theoretical and about 0.55 degree centigrade feet per watt higher.

A more elaborate set of tests recently has been made by the Johns-Manville Company in which temperatures were measured at many more points around the cable sheath, and around the inner and outer surfaces of the enclosing fibre or Transite ducts. These tests involved a fibre duct in air, a fibre duct in a concrete envelope, a Transite (Korduct) duct in air, and a Transite duct in concrete envelope. The results, extrapolated back to a $Q = 10$ watts per foot, are likewise given in Table II and are spotted in Figure 2. It will be noted that the point for fibre duct in concrete falls on the curve through the Barenscher[9] points.

It is significant to observe from Table II that the thermal resistance between

Table II. Values of H_{sd} and H_{sd}' Obtained by Tests on Fibre and Transite Ducts

Q Watts Per Foot	D_s Inches	D_d Inches	H_{sd} Degrees Centigrade Foot Per Watt	*H_w Degrees Centigrade Foot Per Watt	H_{sd}' Degrees Centigrade Foot Per Watt	Condition	Source
10	0.69	3.50	4.70			Fibre duct in concrete	Reference 9
	1.13		3.35				
	2.13		2.70				
	3.13		1.50				
10	3.38	3.88	1.54	0.21	1.75	Fibre duct in air	Johns-Manville Company
			1.40	0.41	1.81	Fibre duct in concrete	
			1.25	0.15	1.40	Transite duct in air	
			1.07	0.13	1.20	Transite duct in concrete	

*The effective thermal resistivity of the duct wall may be determined from the expression

$$\rho_w = \frac{H_w}{0.012\log_{10}\dfrac{4.50}{3.88}} = 1{,}280H_w = \begin{array}{l}\text{400 degree centigrade centimeters per watt for fibre ducts}\\ \text{180 degree centigrade centimeters per watt for Transite ducts}\end{array}$$

cable sheath and the inside of the duct wall increases with an increase in thermal resistivity of the duct material. This is probably due to the departure of the duct wall from an isothermal surface. The data permit the projection of curves representing H_{sd} for fibre and Transite ducts. It may be presumed that the curve of equation 22 is a reasonably good representation in case of a terra-cotta duct which has a thermal resistivity of 100 degree centigrade centimeters per watt, as opposed to 180 degree centigrade centimeters per watt for Transite, and 400 degree centigrade centimeters per watt for fibre.

In the case of fibre and Transite ducts, it is most convenient to care for the additional thermal resistance of the duct wall itself by formulating H_{sd}' to include this resistance. Such curves are shown in solid section in Figure 2. In using these curves, r_d in equation 6 should be taken properly as the outside radius of the fibre or Transite duct, although practically this refinement is unnecessary. For most purposes, equation 9 may be used with β equal to 800 degree centigrade square centimeters per watt for terra-cotta ducts, 1,000 for Transite ducts, and 1,200 for fibre ducts.

It will be evident that a considerable amount of further work can be done profitably in this connection. The accuracy of the curves of Figure 2, however, probably is consistent with the accuracy with which the other components of the thermal circuit can be calculated.

Working Equations

As a practical matter, the separate calculation of R_d is somewhat laborious. The over-all procedure is simplified by setting up the working equations in terms of r_d the radius of a duct, d the distance between adjacent duct centers, and a factor F which is a function of the relative positions of the loaded ducts in the duct structure. The corresponding transformation of equation 5a is developed in Appendix III.

The complete over-all expression for the temperature rise of the surface of the given cable is therefore

$$\Delta T_s = 0.00411\,\frac{Q_c\beta}{D_s} + 0.012\,\frac{Q_d'}{N}\,\rho_d \times \left(N\log_{10}\frac{2L}{d} + \log_{10}\frac{d}{r_d} - F\right) + 0.012Q_d'\left[(\rho_e-\rho_d)\log_{10}\frac{2L}{R_d} + (\rho_p-\rho_e)\log_{10}\frac{L}{L-p}\right] \text{ degrees centigrade} \quad (10)$$

in which

β = 800 degree centigrade square centimeters per watt for terra-cotta ducts
1,000 degree centigrade square centimeters per watt for Transite ducts
1,200 degree centigrade square centimeters per watt for fibre ducts (11)

$$F = f_{12} + f_{13} + f_{14} \quad (12)$$

where the N-1 values of f for each loaded duct in respect to the reference loaded duct may be obtained from Figure 3. Values of F are shown in Figure 1 for the configurations there represented.

If a single equivalent value of thermal resistivity is used from the duct wall out, the last term (in brackets) of equation 10 becomes equal to zero.

The temperature rise of an idle duct is found by eliminating the first term in equation 10 and making $r_d = d$. The factor F will in this case be composed of N values of f.

A typical calculation for six equally located cables in a 2 by 3 duct bank is given in Appendix IV.

Comparison with Present Methods

The common method of calculating the temperature rise of cables in duct, and that adopted by the Insulated Power Cable Engineers Association,[10] is based on the use of equation 9 with β = 1,200 degree centigrade square centimeters per watt (for $D_s > 1.75$ inches) and the familiar National Electric Light Association duct constants.[8]

$$\Delta T_s = 0.00411Q_c\frac{\beta}{D_s} + Q_d'H \text{ degrees centigrade} \quad (13)$$

For a cable diameter of 2.5 inches the first term equation 13 represents a thermal resistance of 1.97 degree centigrade feet per watt, as contrasted with the corresponding value of 1.30 degree centigrade feet per watt obtained from equation 22. There has been considerable confusion as to the true significance of the first term of equation 13, but it is generally agreed that it represents a thermal resistance higher than that defined by H_{sd}. Hence

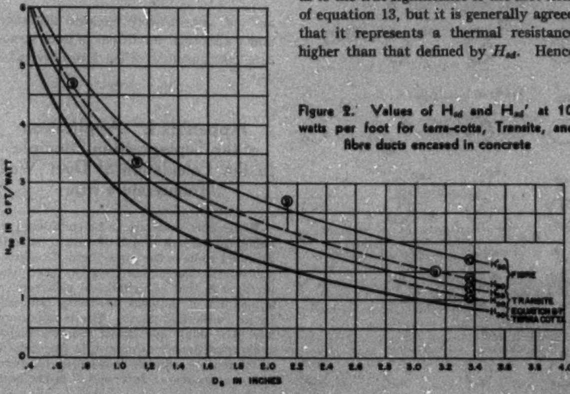

Figure 2. Values of H_{sd} and H_{sd}' at 10 watts per foot for terra-cotta, Transite, and fibre ducts encased in concrete

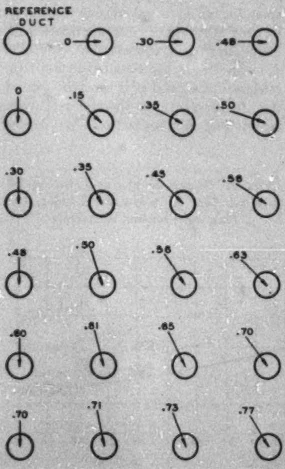
the duct constant H must represent a thermal resistance lower than that from the loaded duct wall to ambient. The value of the thermal resistance, $0.012\ \rho'\log_{10}(2L/R_s)$, represented by the second term of equation 3, on the other hand, involves the applicable value of the effective thermal resistivity of the earth ρ' and the geometry of the duct bank, which are inherently contained in the duct constant H.

While no true comparison can be made, therefore, it is well to note that, assuming a value of 75 degree centigrade centimeters per watt for ρ', $D_s=2.5$ inches, and the geometry given in Table I which is typical of average practice at the time the duct constants were formulated, the resultant values of the effective thermal resistance between sheath and ambient on a per-cable basis, H_{sa}, as calculated by equations 3 and 22 and as spotted on Figure 4 check reasonably well with the curve of equation 13 shown in the figure. For three or more loaded ducts the agreement is within 10 per cent, which is in the same order as the theoretical variations caused by a change in cable configurations for the same number of loaded ducts, and which is well within the variations which may be expected in ρ' for different locations.

For normal situations where ρ' has not actually been determined, therefore, a working figure of 75 degree centigrade centimeters per watt appears to be consistent.

Figure 3. Relative position factors f for ducts in a duct bank



Conclusions

1. The basis for a theoretical method of calculating the temperature rise of cables in duct in terms of the geometry of the duct bank and the effective thermal resistivity of the earth has been indicated. The method is essentially simple and readily understandable. The slight additional labor involved over the conventional method is more than compensated by the increased accuracy of the method.

2. The accuracy of the method is dependent upon the refinement with which the basic quantities involved can be determined. Such refinements, involving further basic research and tests, have been indicated. At the present time sufficient data has been presented to permit calculations of equal accuracy with conventional methods under normal conditions, and of considerably greater accuracy under abnormal conditions of duct structure, configuration, or earth resistivity.

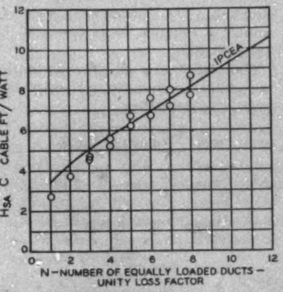


Figure 4. Comparison of H_{sa} as calculated for a 2.5-inch diameter cable and 75 degrees centigrade per watt thermal resistivity with the Insulated Power Cable Engineers Association values

Appendix I. Application of the Superposition Principle to the Calculation of Duct Wall Temperature Rise

If the duct walls are to be considered as being isothermal, and if the duct bank is assumed to have the same thermal resistivity as the surrounding earth, then the problem is that of cylindrical radiators in a medium of uniform resistivity bounded by an isothermal plane. The temperature rise of a single cylindrical radiator under these conditions is developed in Appendix I of reference 4, wherein it is shown that the temperature rise at any point P in the heat field of the radiator is given by the expression

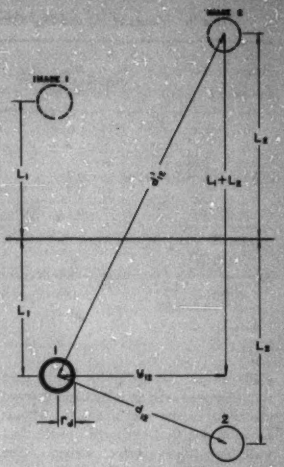

Figure 5. Development of the temperature rise of a duct wall by the principle of superposition

$$\Delta T_p = 0.012\rho Q \log_{10} d'/d \quad \text{degrees centigrade} \tag{14}$$

where d is the distance of the point from the thermal center of the radiator and d' is the distance of the point from the image of the thermal center of the radiator. If the radius r_d of the radiator is small in respect to twice its depth L below the isothermal plane, as is true in this case, the thermal center coincides practically with the physical center of the radiator.

The principle of superposition merely states that the temperature rise at any point such as P because of the simultaneous operation of a number of such radiators, is equal to the sum of the temperature rises produced at P by each radiator operating as if the other radiators were absent.

Consider the case of two such radiators located as shown in Figure 5, at depths L_1 and L_2 below the isothermal plane and liberating Q_1 and Q_2 watts per foot respectively. By the application of equation 14 and the superposition principle, the increase in temperature rise of radiator *1* due to the simultaneous operation of radiator *2* is given by the expression

$$\Delta T_{12} = 0.012\rho Q_2 \log_{10}\frac{d_{12}'}{d_{12}} \text{ degrees centigrade}$$
$$= 0.012\rho \times \left[Q_2 \log_{10}\frac{\sqrt{(L_1+L_2)^2+y_{12}^2}}{d_{12}}\right] \text{ degrees centigrade} \tag{15}$$

In the case of a duct structure, the maximum value of y is relatively small with respect to $2L$ so that d_{12}' may be taken equal to L_1+L_2. Thus the temperature rise of an isothermal duct wall due to the combined effect of all occupied ducts is

$$T_{d1}=0.012\rho\left[Q_1 \log_{10}\frac{2L_1}{r_d}+ Q_2 \log_{10}\frac{L_1+L_2}{d_{12}}\ldots+ Q_n \log_{10}\frac{L_1+L_n}{d_{1n}}\right] \text{ degrees centigrade} \quad (4)$$

Appendix II. Thermal Resistance between Cable Sheath and (Isothermal) Duct Wall

The mechanism of heat transfer between a cylindrical radiator and an enveloping isothermal enclosure through an intervening fluid medium is such that a portion of the total heat flow Q is carried by convection Q_{cv}, a portion by conduction Q_{cd}, and the remainder by radiation Q_r. In formulating the components of the thermal circuit, therefore, it is more convenient to work in terms of thermal conductances rather than thermal resistances, since the former quantities are directly additive. Thus, if ΔT is the temperature drop in degrees centigrade across the circuit

$$\frac{Q}{\Delta T}=\frac{Q_{cv}}{\Delta T}+\frac{Q_{cd}}{\Delta T}+\frac{Q_r}{\Delta T} \text{ watts per degree centigrade foot} \quad (16)$$

The phenomenon of convection involves the conception of the temperature drop being concentrated in two films, one at the surface of the cylindrical radiator, of diameter substantially equal to the diameter of the radiator D_s in inches; and one at the surface of the enclosing isothermal surface, which also will be considered as being cylindrical of diameter D_d. The following equation, based on McAdams' equation 42, page 254,[11] (first edition only) is applicable to either film when the fluid is air at atmospheric pressure and at 50 degrees centigrade.

$$Q_{cv}=0.092D_f^{3/4}\Delta T_f^{5/4} \text{ watts per foot} \quad (17)$$

The effect of normal temperature variations from 50 degrees centigrade is minor. The solution of equation 17 for the two films in series is given with sufficient accuracy by the expression

$$\frac{Q_{cv}}{\Delta T}=0.092\frac{D_s^{3/4}\Delta T^{1/4}}{1.39+D_s/D_d} \text{ watts per degree centigrade foot} \quad (18)$$

From a theoretical standpoint the expression for the conduction component should take into account any eccentricity between the cylindrical radiator and the enveloping isothermal enclosure. In the practical case of a cable in duct, the cable will not rest uniformly on the bottom of the duct, and also, in the case of a nonmetallic duct, the duct wall is not strictly maintained as an isothermal. Since these effects cannot be evaluated, the familiar expression for the resistance between two concentric cylinders in terms of the dimensions of the cylinders and the thermal resistivity of the medium, which has been taken as 3,900 degree centigrade centimeters per watt, will be used

$$\frac{Q_{cd}}{\Delta T}=\frac{0.0213}{\log_{10} D_d/D_s} \text{ watts per degree centigrade foot} \quad (19)$$

The radiation component is given with sufficient accuracy by the following expression based on McAdams' equation 17, page 63,[11] (second edition)

$$\frac{Q_r}{\Delta T}=0.102D_s\epsilon(1+0.0167T_m) \text{ watts per degree centigrade foot} \quad (20)$$

in which ϵ is the emissivity coefficient of the surface of the cable, and T_m is the average temperature of the air in the duct in degrees centigrade. Experience has indicated that the value of ϵ may be taken as 1.00. Thus, for an air temperature of 50 degrees centigrade, equation 20 becomes

$$\frac{Q_r}{\Delta T}=0.187D_s \text{ watts per degree centigrade foot} \quad (21)$$

Combining equations 16, 18, 19, and 21, we obtain for H_{sd}, the thermal resistance between cable and duct wall

$$H_{sd}=\frac{10.9}{\dfrac{D_s^{3/4}Q^{1/4}H_{sd}^{1/4}}{1.39+D_sD_d}+\dfrac{0.232}{\log_{10} D_d/D_s}+2.04D_s} \text{ degree centigrade feet per watt} \quad (22)$$

It will be seen that the primary variable in equation 22 is D_s. Since variations in Q, D_d, and T_m have minor effects on the final result, it is sufficient for practical purposes to assume average values for these quantities of 10 watts per foot, 4 inches, and 50 degrees centigrade, respectively. The resulting solution of equation 22 is plotted as the heavy curve in Figure 2.

Appendix III. The Relative Position Factors *F* and *f*

Equation 5a may be written as

$$\begin{aligned}\Delta T_d&=0.012\rho\frac{Q_d'}{N}(N\log_{10}2L- \log_{10} r_d-\log_{10} d_{12}-\log_{10} d_{13}\ldots)\\ &=0.012\rho\frac{Q_d'}{N}(N\log_{10} 2L- \log_{10} r_d+\log_{10} d-N\log_{10} d-\log_{10}\frac{d_{12}}{d}- \log_{10}\frac{d_{13}}{d}-\log_{10}\frac{d_{14}}{d}\ldots)\\ &=0.012\rho\frac{Q_d'}{N}\left(N\log_{10}\frac{2L}{d}+\log_{10}\frac{d}{r_d}-F\right)\end{aligned} \quad (23)$$

where

$$F=f_{12}+f_{13}+f_{14}\ldots \quad (12)$$

$$=\log_{10}\frac{d_{12}}{d}+\log_{10}\frac{d_{13}}{d}+\log_{10}\frac{d_{14}}{d}\ldots$$

The value of f for any relative position of a loaded duct with respect to the reference duct may be obtained from the diagram shown in Figure 3.

Appendix IV. The Solution of a Typical Problem

Given six 2.5-inch diameter equally-loaded cables with a loss factor of 0.85, located in a 2 wide by 3 deep duct bank consisting of 4.5-inch fibre ducts on 8.5-inch centers encased in concrete with over-all dimensions of 20 inches wide by 28.5 inches deep, and installed with a 30-inch cover of which 10 inches is concrete pavement, determine H_{sa} for a middle (hottest) duct.

> $r_d=2.25$ inches, $d=8.5$ inches, $D_s=2.5$ inches, $\beta=1{,}200$ degrees centigrade square centimeters per watt (equation 11); $F=0+0.15+0+0.15+0=0.30$ (equation 12 and Figure 3); $R_b=0.112\times2(20+28.5)=10.9$ inches (equation 8); $L=30+1/2\times28.5=44.3$ inches, $p=10$, $N=6$. Assume $\rho_d=100$, $\rho_c=65$, and $\rho_p=100$ degree centigrade centimeters per watt.
>
> By equation 10

$$\begin{aligned}H_{sa}=\frac{\Delta T_s}{Q_c}&=\left(\frac{0.00411\times1{,}200}{2.5}\right)+ (0.012\times0.83\times100)\times \left[\left(6\log_{10}\frac{88.6}{8.5}\right)+\left(\log_{10}\frac{8.5}{2.25}\right)-0.30\right]\\ &\quad+(0.012\times6\times0.85)\times \left[\left(-35\log_{10}\frac{87.6}{10.9}\right)+\left(35\log_{10}\frac{88.6}{78.6}\right)\right]\\ &=1.97+(0.012\times0.83\times100)(6.39)+ (0.012\times6\times0.85)(-30.0)\\ &=6.64 \text{ thermal ohm feet}\end{aligned}$$

If we assume an effective $\rho'=75$ degrees centigrade centimeters per watt

$$H_{sa}=\frac{\Delta T_s}{Q_c}=1.97+(0.012\times0.85\times75\times6.39) =6.86 \text{ thermal ohm feet}$$

present methods, equation 13

$$H_{sa}=\frac{\Delta T_s}{Q}=1.97+(0.85\times4.92) =6.15 \text{ thermal ohm feet}$$

Note that, for a corner duct, $F=0.80$ and H_{sa} becomes 6.14 thermal ohm feet.

Discussion

Robert J. Wiseman (The Okonite Company, Passaic, N. J.): This paper by Mr. Neher helps to appreciate the various parts of the thermal circuit of a duct bank. A few years ago some of us, as members of a Subcommittee of the Power Transmission and Distribution Committee, engaged in a discussion as to what was meant by the duct heating constants which we use, and what earth thermal resistivity was associated with these constants. For a proper analysis, the structure of the duct bank and the position of the cables in the ducts have to be considered. The author has done a very nice piece of analysis of this problem and offers a method for future use. I think we should seriously consider his suggestions and decide if we are to adopt them or continue as we do now.

At the present time, the duct constants do not differentiate between the number of cables in a duct bank and the number of ducts, whereas the author shows us what the difference is, by what he calls close and loose configuration. As the allowable current is determined by the hottest cable, this current can be more accurately determined by using the author's method for calculating the duct bank thermal resistance. If the author's suggestions are adopted, the Insulated Power Cable Engineers Association's current loading tables will have to be revised. Before doing so, it seems advisable for both the Insulated Conductor Committee and the Insulated Power Cable Engineers Association to consider the matter.

The author makes several assumptions in order to arrive at reasonably simple methods of calculation. This is acceptable, provided assumptions do not go too far. Under Appendix IV he gives an example of how to use his method for computing the thermal resistance. I note that he uses a value of ρ for earth as 65 thermal ohm centimeters and then gives a new value for H_{sa} if $\rho = 75$ is taken assuming installation under paved areas. He shows in his paper that by using this value he obtains values of H_{sa} closely the same as for Insulated Power Cable Engineers Association's duct heating constants. Several years ago some of us who were studying this subject showed by very simple methods that the duct constants gave an apparent thermal resistivity of 65–75 thermal ohm centimeters and stated that if this were correct, we should use the same value for buried cables or pipes. We are not doing so, but using a value of $\rho_s = 80$. To be consistent, we should use $\rho_s = 80$ for duct systems also or revise both duct and buried pipe to $\rho = 65$, if in uncovered earth, or $\rho = 75$ if under paved areas. I hope that the Insulated Conductor Committee and Insulated Power Cable Engineers Association will take action to establish a uniform value for ρ when applied to duct or pipe cables.

This paper, along with the one previously presented, on buried cables and pipes,[1] have helped to show how the two systems compare thermally. It is up to us to take advantage of his investigation of the subject by accepting as our standard, his recommendations for methods of calculating the thermal resistance of ducts and buried cables with the correct thermal constants.

F. H. Buller (General Electric Company, Schenectady, N. Y.): Mr. Neher has again presented an interesting and valuable analysis of the problem of underground cable heating. This time he covers the case of cables in ducts. Some of the points which he brings up, however, would seem to merit a little further consideration.

First, there is the calculation of R_d and R_b. Mr. Neher evaluates these radii by the use of the principle of superposition, which leads to formulas involving the geometric mean distance between the cable under consideration and the other cables in the duct bank.

The principle of superposition is indeed a powerful tool whereby complicated problems can be greatly simplified; but it does have certain limitations. I propose to draw attention to a couple which are pertinent to the present study.

The first one is fundamental. The principal of superposition is rigorously valid only for situations where the effect is proportional to the cause. To illustrate this point, consider a current flowing through a resistance. If the resistance is constant, the voltage drop is given by Ohm's law $E = IR$. Here the effect (voltage drop) is proportional to the cause (current) and we would expect the superposition principle to apply, which it does. Double the current, and the voltage drop is doubled.

Now consider the loss in the same circuit. This is given by Joule's law — $W = I^2R$. Here the effect (watts loss) is not proportional to the cause (current) but to the square of the cause, and the principle of superposition cannot be expected to apply. Double the current, and the watts loss instead of being doubled, is quadrupled.

So long as Mr. Neher is dealing with thermal conduction, the superposition principle should apply. When he is considering the temperature rise in a duct due to losses in another loaded duct, convection and radiation come into the picture as well, in both ducts under consideration. In these phenomena the effect (temperature rise) is not proportional to the cause (heat flow). (See Mr. Neher's reference 11 and his Appendix II.) Hence the use of superposition in deriving equations 4 to 7 is at best an approximation.

The second limitation is practical. Before one can superpose several effects at any point, one must calculate these effects individually at that point. This is often a fairly straightforward process in a homogeneous medium; but the cross section of a duct bank is unfortunately far from homogeneous. The thermal resistance of the empty duct is much higher than that of the concrete; and the presence of metallic materials in the duct would on the other hand tend to reduce its thermal resistance. All this distorts the thermal field, thus placing Mr. Neher in the position of a man who tries to calculate the magnetic reluctance of a perforated steel plate in which some of the holes are partly filled with iron filings. This is a difficult problem; and the answer would not be the same as for a homogeneous unperforated steel plate, even if there is no saturation so that superposition could be applied directly. Thus, Mr. Neher's technique contains two approximations.

It also contains a third approximation which is introduced by the fact that the duct walls are not isothermals. This third approximation is at least as important as the other two.

Thus it would seem that Mr. Neher's technique of calculation R_d and R_b is actually no more rigorous than the equivalent periphery method even though it is based on the principle of superposition. However, it is reassuring to note that the two methods check within 10 per cent. If these radically different methods check so closely, the answers which they give should not be very far from the truth.

The man who wants to use Mr. Neher's results effectively would do well to subject the section Comparison with Present Methods in the paper to the most careful scrutiny. A careless reading of this section would give the impression that Mr. Neher believes that a soil thermal resistivity of 75 is the value on which the Insulated Power Cable Engineers Association's duct constants are based.

A more careful reading reveals that this is not the case; he has simply pointed out that if this value is used in his equations in combination with a cable diameter of 2.5 inches and a β value of 1,200, the values obtained by the Insulated Power Cable Engineers Association's method for H_{SA} will be checked within 10 per cent (see Figure 4 of the paper). This statement is correct; but it is not at all the same thing as saying that a value of 75 is representative for the soil thermal resistivity on which the

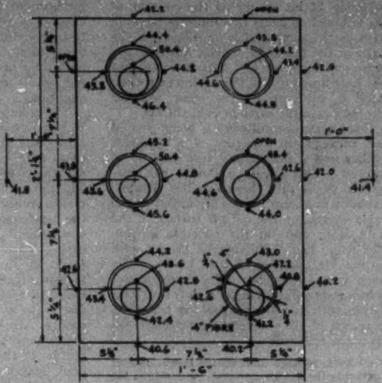

Figure 1. Temperature readings in concrete duct run in air

Cable outside diameter 2.52 inches. Chloroprene sheath. Loss=3.0 watts per foot per cable. Temperatures in degrees centigrade

Insulated Power Cable Engineers Association's duct constants are based.

The Insulated Power Cable Engineers Association also uses a value of $\beta = 1{,}200$; but all the test data on which their values of H are based were taken in outside idle ducts. Thus the value of $\beta = 1{,}200$ includes all the thermal resistance from the outside idle duct to the cable sheath; and a goodly portion of this thermal resistance occurs in the duct structure itself. This is borne out by various field tests made by different observers. The British get a value of about 675 for β, measured to the air of the loaded duct. Herman Halperin[1] gets something below 550 and other tests yield similar values. On the other hand for the portion of the thermal resistance in the duct structure itself W. B. Kirke[2] gets 0.75 degree centigrade per watt per foot; G. B. Shanklin in an unpublished memorandum on the Insulated Power Cable Engineers Association's duct constants obtains 1.32; and a recent heat run gave a value of 1.13 for one particular case. Since the soil heating term in Mr. Neher's formula is carried up to the loaded duct wall, these figures should be added to the Insulated Power Cable Engineers Association's duct constants when checking back on the soil thermal resistivity. If this is done the soil thermal resistivity in Mr. Neher's formulas which would check the revised Insulated Power Cable Engineers Association's duct constants when these are carried up to the loaded duct wall will be of the order of 100; and the difference between Mr. Neher's geometric mean distance method and the equivalent periphery method of calculating R_d and R_b could add another 10 per cent to this value.

To sum this point up, a soil thermal resistivity of 75 and a β value of 1,200 should be used in Mr. Neher's formulas to check sheath temperatures as obtained by the Insulated Power Cable Engineers Association's method, and to extend this method to other duct configurations; but these figures, while they fit the formulas, should be regarded as empirical coefficients rather than true thermal resistivity values. The true soil thermal resistivity which should be used in comparing performance of duct cables with buried cables and other buried systems is likely to be considerably higher than this.

If an exact comparison is required between the potential performance of duct cables and buried cable systems along some particular route, it is well to make a field survey covering the entire length of the projected cable line, at a dry season of the year; and even then a reasonable allowance should usually be made for a potentially drier season. If some point along the line is found to have a higher soil thermal resistivity than the rest of the line, either this point should be taken as the criterion, or oversized copper should be installed there, and the next hottest spot taken as the criterion of comparison.

Frank V. Smith (Sargent and Lundy, Chicago, Ill.): A paper of the type that Mr. Neher has written has been needed for a long time. The inadequacy of the duct heating constants have been apparent to all those who have worked with them. The industry owes a debt of gratitude to Mr. Neher for the patience and perserverance he has shown in going through the great mass of historical material available in order to distill from it a method of analysis that it is hoped will be generally acceptable.

The degree of accuracy of any method of calculating the heat flow through duct structures and the earth cannot be too high, but what is important is that there be general agreement on the method of analysis and a proper sense of proportion so that the same approach can be used in making studies of alternate ways of handling a specific problem.

The duct heating constants were based on average conditions and were not designed to take account of changes in duct geometry, depth below the surface, earth resistivity, and so forth, factors which are different for every application. Large organizations have developed techniques suitable for their own local conditions, but it has not been possible to make these all consistent with one another.

Mr. Neher has discussed each of the debatable points in following the heat flow from the cable sheath to the earth and has produced a logical method of analysis with supporting data.

Mr. Neher's major contributions are:

1. Clarification of the thermal drop from the cable sheath to the duct wall. The experimental material in this field is still meager and additional test data are desirable.

2. A method of calculating the relative thermal resistances from various duct positions to earth. The method is based on a group of loaded ducts in a completely uniform medium and is to that degree an approximation, but still it does give reasonable results that allow differentiation between the temperature rises of different ducts in a bank. Additional test data here, too, would be welcome.

The effect of two of the factors ignored by the duct heating constants might be noted from an examination of Appendix IV of the paper. Here for a 6-duct run with 30-inch cover and earth with a thermal resistivity of 65, the total thermal resistance from the hottest cable sheath to the earth is calculated to be 6.64 thermal ohms per foot. If the cover were increased to 60 inches, the same method of analysis would show that the thermal resistance has increased to 7.45 thermal ohms, or a matter of 12 per cent. If the earth resistivity were doubled to 130 (a not unlikely figure), the thermal resistance will be found to increase to 10.05 thermal ohms per foot, or a matter of some 58 per cent. Such changes clearly make important differences in the temperature rise and cable rating.

We would like to comment on the application of the method to the case of a concrete duct run suspended in air. This is a situation that exists frequently in power station design where important generator leads may be carried through turbine rooms and boiler rooms. The paper is concerned with a duct bank in earth and the formulas are set up with this situation in mind. It will be noted that the second term in equation 1 could be written

$$0.012Q_d'\rho_d \log_{10}\frac{R_b}{R_d}+0.012Q_d'\rho_e \log_{10}\frac{2L}{R_b}$$

The first term could be interpreted as the thermal resistance from the loaded duct wall to the surface of the concrete and the second term as the thermal resistance from the surface of the concrete to the earth. If this were done in the case of Appendix IV of the paper, the distribution of thermal resistances would be as follows:

	Thermal Ohms
Sheath to duct wall	1.97
Duct wall to concrete surface	.95
Concrete surface to earth	3.72
Total	6.64

If the duct run were suspended in air, the last term would disappear and would be replaced by one giving the thermal drop from the concrete surface to the air, such as

$$Q_d'\frac{0.00411\pi\beta}{P_b}$$

where β is considered by the heating and ventilating engineers to be about 1,000 for still air and 300 for air moving at 22 feet per second.

Mr. Neher might not quite agree with this adoption of his theory as the concept of R_4 is based on ducts in a uniform medium such as the earth and is developed on the basis of the theory of images, but common sense and available test data indicate that the heat flow through the concrete duct run itself is substantially the same whether the duct is in the earth or is in the air.

Some experimental work is being carried out through the courtesy of a Midwest Utility and a preliminary test may be of interest. This covers a 6-duct run suspended in air with thermocouples installed as shown in Figure 1 of the discussion on the cable sheath, on the outside surface of the duct wall, and on the concrete surface. The cable had a chloroprene sheath with an outside diameter of 2.52 inches. The ducts were 4-inch fibre. The temperatures shown were obtained under steady load conditions with 3.0 watts per foot loss per cable. A review of the temperature readings will show the following:

> Using the average cable sheath temperature in relation to the average duct wall temperature, the value of β for the cable sheath becomes 1,020.
>
> Using the average duct wall temperature of the four corner ducts in relation to the average concrete surface temperature, the thermal resistance from duct wall to surface is 0.11 thermal ohms. (A calculation according to Mr. Neher's method using ρ for concrete of 100 would give 0.08 thermal ohms.)
>
> Using the average duct wall temperature of the two center ducts in relation to the average concrete surface temperature, the thermal resistance from a center duct wall to the surface is 0.16 thermal ohms. (Calculation according to Mr. Neher's method would give 0.19).
>
> Unfortunately ambient air temperatures were taken only at the sides of the duct run rather than also the top and bottom so that the average drop from concrete surface to air is not available, but the temperature drop from the sides of the concrete structure to the air in that vicinity shows an average temperature difference of 1.3 degrees centigrade which would correspond to β for the concrete surface of 480.

Paul Greebler (Johns-Manville Research Center, Manville, N. J.): Mr. Neher, in his paper, refers to tests conducted at the Johns-Manville Research Center on Transite and fiber duct. Although we plan in a forthcoming paper to give a complete discussion of the method and results of the tests, I would like at this time to give a brief description of the test assembly together with some practical calculations based upon our results and using Mr. Neher's working equations.

The cross-section detail for ducts encased in concrete in Figure 2 of the discussion shows the thermal heat flow components that were studied. The $3^1/_2$ inch lead sheath encloses a centered Calrod heater. Thermocouples for temperature measurements are located on the sheath surface, on the inside and outside duct wall surfaces, and around the outside of the concrete casing. Tests were conducted both for ducts in air and in concrete, the cross-section detail for the "in-air" tests being identical with that shown in Figure 2 of the discussion with the absence of the concrete casing. An 8-foot length of duct was used, measurements being made on a 2-foot test section in the center, the remainder of the duct length being employed as thermal guards to eliminate end effects. This test section might seem somewhat short. However, the many years experience in conducting thermal tests at Johns-Manville has shown that a small sample, properly guarded against end effects, gives results identical with those from a large sample.

The most critical measurements in the tests were those of the inside and outside duct wall surface temperatures. Figure 3 of the discussion shows the thermocouple assembly on the outside of a test section of fiber duct. There are 48 couples spaced around each surface in the form of a 3-turn helix with 16 couples per turn. The constantan wires are soldered to a thin copper strip cemented to the duct wall. They are run for about two inches along the duct surface, and then inserted into fine holes carrying them inside the duct. All constantan leads were carried through the inside of the duct to avoid abrasion when set in concrete.

Table I. Current Rating Calculations

3 Conductor, 500,000-Circular-Mil Compack Sector, 203 Mils Paper, 125 Mils Lead, 15-kv Grounded Neutral (6th Edition AEIC Specification)

Number of Loaded Ducts*	Amperes per Conductor		
	Transite	Fiber	Ratio: Transite/Fiber
One	456	423	1.078
Three	386	365	1.056
Six	325	312	1.042

* These calculations are based upon inside and outside duct wall surface diameters of 4.00 and 4.62 inches, a 30-inch cover, spacing of 6.6 inches between duct centers, and a 2-inch layer of concrete over the ducts. A 20-degree-centigrade earth ambient and a 75 per cent daily load factor are assumed.

Current rating calculations of cable in Transite and fiber duct, applying Mr. Neher's working equation with a 75 degrees centigrade centimeters per watt thermal resistivity outside the duct wall, are shown in Table I of the discussion. Thermal surface resistivity factors of 1,020 and 1,200 degrees centigrade square centimeters per watt are used respectively for Transite and fiber, these β values being based upon a heat flow of ten watts per foot and averaged for the tests in air and in concrete. The additional thermal resistance of the duct wall itself is considered by adding the term,

$$0.012\rho_w \log_{10} \frac{D_o}{D_i} \text{ where } D_o \text{ and } D_i \text{ are}$$

the outside and inside duct wall diameters, and ρ_w, the duct wall thermal resistivity, is 200 degrees centigrade centimeters per watt for Transite and 480 degrees centigrade centimeters per watt for fiber. These values are higher than those given by Mr. Neher in Table II of his paper since they are based upon two sets of tests, the calculations from the second test series having been completed too late for consideration by Mr. Neher in his paper. The ratio of current rating in Transite duct to that in fiber duct, shown in the third column of Table I of the discussion measures the practical effect of the duct wall thermal resistivity for one, three, and six loaded cables in a duct bank. The decrease in current rating ratio with increasing number of loaded ducts measures the rate at which the influence of the duct wall upon the thermal path decreases as the number of loaded cables in the duct bank increases.

J. H. Neher: I am greatly indebted to the various discussers for reviewing the background of this problem, which explains in some measure why this particular paper has been written. The additional data presented by Mr. Smith and by Mr. Greebler on the thermal resistance between cable sheath and duct wall is most interesting and I am pleased to see how close an agreement is obtained between the measured and calculated difference between average duct wall temperature and average bank periphery temperature from Mr. Smith's data. This is a difficult part of the thermal circuit to calculate and fortunately it represents only a small part of the total.

It appears that the β values of 1,020 for Transite and 1,200 for fiber to the inside of the duct wall which Mr. Greebler derives from his tests, were obtained on the basis of a 3.5-inch cable in a 4-inch duct. I have indicated in the paper that the variation of H_{sd} with cable diameter is fundamental and that the derived quantity β is only approximately constant and increases with cable diameter. Hence if one insists in using β for convenience, β should be determined on the basis of an average size cable. The cable in this particular test was unusually large. A more representative cable size was used in determining the working values as given in the paper which, incidentally, include the additional drop through the duct wall.

The value of 1,020 which Mr. Smith derives from his data for a fiber duct is presumably to the outside of the duct wall and is based on an average size cable, but on a lower than average heat flow, the effect of which is to increase slightly the value obtained. Thus we must conclude that Mr. Smith's value for a fiber duct is some 20 per cent lower than that given in the paper. It is hoped that further test data of this type will soon become available so that the accuracy of this part of the calculation may be improved. Here again, however, H_{sd} represents a relatively small part of the total thermal circuit in the usual case.

Mr. Buller has nicely stated the limitations of the principle of superposition, and he has pointed out quite rightly that my solution of the problem involves three basic assumptions.

(1) The thermal resistivity at any point in the heat field is independent of the temperature existing at that point.

(2) The difference in effective thermal resistivity of the loaded or empty ducts from that of the duct structure may be neglected.

(3) The duct walls may be treated as isothermal cylinders.

The use of assumptions in the solution of a problem of this type is unavoidable, but the relative merit of the solution depends on whether these assumptions are the best that can be made and to what degree they are valid. These assumptions apply primarily within the duct structure. Beyond the duct structure the first assumption might be involved as a result of moisture migration, but as indicated in reference 1 of the paper, this effect is negligible because of the relatively large effective radius of the duct structure.

As indicated in the paper the errors introduced by all these assumptions may be evaluated by a number of carefully controlled tests and appropriate correction factors developed which would increase the accuracy of the procedure. Both theory and experience indicate, however, that a relatively small portion of the total thermal drop exists between the loaded duct walls and the duct bank periphery. The first two assumptions are, therefore, found to be essentially valid. It will be noted that Mr. Buller's preferred "equivalent periphery" method makes use of these same approximations.

The equivalent periphery method, however, is entirely arbitrary in its evaluation of the effective radius of the loaded duct walls, and one might equally well argue that the boundary should be drawn inside of empty outside ducts, or even that the solution should be based on the enclosed area rather than on the perimeter. On the other hand the method given in the paper is theoretically correct for the assumptions which have been made. A given problem may be solved just as quickly by the working equations given in the paper as by the equivalent periphery procedure.

The third assumption also is reasonable. The abrupt decrease in thermal resistivity occurring at the duct wall tends to equalize the temperature around the wall, as is indicated by the test data cited in the paper and presented by Mr. Smith. Furthermore as Mr. Buller has mentioned, there is a change in the mechanism of heat transfer at the duct wall which establishes it as a natural reference point in formulating equations for the overall thermal circuit.

In the Insulated Power Cable Engineers Association's procedure, the reference point was taken to be the air in outside idle ducts. This is not an altogether suitable bench mark, because the thermal resistance between it and the cable sheath is not only variable, but is a composite relationship which is difficult to deal with analytically. While experience has indicated that the Insulated Power Cable Engineers Association's procedure will yield rule of thumb answers which are quite satisfactory for most practical calculations, it is manifestly impossible to derive therefrom separate thermal resistances between sheath and duct wall and between duct wall and ambient earth from which the earth's effective resistivity might be determined. These quantities simply do not exist as distinct entities in the procedure.

The method given in the paper involves both the thermal resistivity of the earth and the geometry of the particular installation. By making the geometry conform to that involved in the formulation of the National Electric Light Association's duct constants, it becomes possible to determine empirically what approximate value of the thermal resistivity would cause this method to yield results comparable to the Insulated Power Cable Engineers Association's procedure. In this determination the value of β was taken as 800 corresponding to terra cotta ducts which presumably were used in the National Electric Light Association's duct constant determination and not 1,200 as Mr. Buller has indicated. The effective value of thermal resistivity thus determined is 75-thermal-ohm centimeters, and the agreement between the two methods is within ten per cent.

This does not mean that one should compare the performance of a pipe-type cable system calculated with a resistivity of 75 and a cable in duct system calculated by the Insulated Power Cable Engineers Association's procedure. One serious deficiency of this procedure is that it does not represent the geometry or the duct material currently used in high-voltage cable in duct installations. Valid comparison requires that both systems be appraised by the use of a method which consistently accounts for all of the significant factors involved.

Mr. Wiseman has indicated that he has been using a value of 80 rather than 75 for the effective earth resistivity in making these comparisons. We too have been using 80 because it more nearly represents the average dry season value obtained by sphere tests on our system. It is important to realize that the point-to-point variation over the system or in fact along a single line far exceeds the difference in these values, and thus the establishment of separate values for installations in covered or uncovered earth is not warranted.

Mr. Wiseman also has suggested the advisability of revising the Insulated Power Cable Engineers Association's current loading tables in the light of the method given in the paper. This would be a considerable procedure due to the number of variable factors involved, for each of which a representative value would have to be established and agreed upon. The resultant values would more nearly represent present duct construction practice, but would not necessarily represent a more accurate cable rating unless the particular geometry and resistivity prevailing happened to coincide with the values used in the preparation of the tables.

This and the preceding paper[1] have been prepared not with the idea of revising the present current loading tables, but to present consistent methods whereby the temperature rise of various specific cable installations might be more accurately calculated, and incidentally more accurately compared.

69-Kv Pipe-Type Cable Circuits in Philadelphia

A. H. KIDDER
MEMBER AIEE

G. S. VAN ANTWERP
ASSOCIATE AIEE

THE Philadelphia Electric Company System has approximately 250 miles of 69-kv circuits, of which 74 miles are installed underground, along routes where right-of-way considerations have precluded using aerial construction. Prior to 1940, the system plans permitted 69-kv underground cable circuits to have ratings of 440 to 525 amperes under conditions satisfied by solid-type paper and lead cable. The 52 miles of underground circuit additions since 1940, including six miles recently contracted for, however, were required to have load ratings in the range from 660 to 880 amperes. Comparative cost studies showed the pipe-type of construction to have a somewhat lower cost than oil-filled cable.

Only one manufacturer would recommend a practical copper size for the desired 880-ampere rating in pipe for projects being planned from 1940 to 1945. The unanswered problems of pipe corrosion and practical cable fault locating techniques in pipe also handicapped the pipe-type systems. Consequently, conventional oil-filled cable was specified for the 13-mile Chester-Upper Darby 660-ampere line installed in 1942, and for the two $4^1/_2$-mile Southwark-Schuylkill 880-ampere lines then in planning stages.

Meanwhile the problems of load rating, pipe corrosion, and cable fault location were actively investigated. The 69-kv experimental Oilostatic cable installation at Plymouth Meeting Substation, in service since 1933, was disconnected in January 1945, and a 19-day 880-ampere low-voltage heat run was started March 1 on one 1,000,000 circular mil, 800-foot section. Thermocouples observed pipe temperature at approximately 100-foot intervals. Copper temperature was observed by d-c resistance measurements, and corrected for the natural temperature decrement during the few minutes interval between the instant of de-energizing the cable and that of each reading obtained. Ambient earth temperature was observed by several thermocouples, some in the earth and others on remote sections of the pipe excluded from the test. The total losses were read by the standard 3-wattmeter method. Figure 1 summarizes this test, from which the thermal resistivity of the earth at this open location was found to be 60 thermal ohm centimeters, or less than the 80 thermal ohm centimeters at which pipe-type circuits could be designed for loads above 800 amperes.

It soon became apparent that the section containing an oil pipe-type cable fault might be identified by the operation of suitable pressure diaphragms installed at the semistop joints and actuated by the transient oil pressure waves accompanying the fault. A more accurate location might then be obtained by use of the high-voltage bridge which has since been secured for this purpose.

Almost concurrently, the pipe corrosion investigations gave needed assurance that a high quality pipe coating should permit maintaining slightly cathodic potentials for preserving the integrity of the steel pipe as a pressure vessel during the expected life of the cable.

Orders for ten miles of 880-ampere oil pipe-type cable circuit were then placed and followed shortly by orders for a 3-mile circuit of similar design. The next project included a 6-mile 880-ampere circuit and two short 560-ampere circuits, all high-pressure gas in pipe through a tunnel constructed under the Schuylkill River. These three projects were completed respectively, ten miles of oil pipe in August 1947, three miles of oil pipe in

Paper 49-136, recommended by the AIEE Insulated Conductors Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer General Meeting, Swampscott, Mass., June 20–24, 1949. Manuscript submitted March 18, 1949; made available for printing April 26, 1949.

A. H. Kidder is Assistant Engineer in charge of Special Investigations and Testing Divisions, and G. S. Van Antwerp is General Superintendent, Transmission and Distribution Department, both with the Philadelphia Electric Company, Philadelphia, Pa.

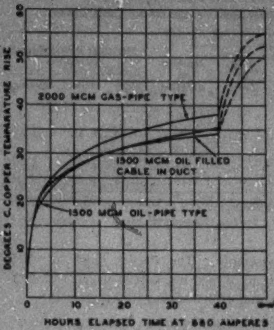

Figure 2. Comparative heating characteristics in 80 thermal ohm centimeter earth

July 1948, and seven miles of high-pressure gas pipe in September 1948.

It seems appropriate now to summarize briefly the significant features of the more interesting 880-ampere pipe-type circuit designs, one circuit using oil and one circuit using gas as the pressure medium for two quite different cable constructions.

Description of the Cables

The 1,500,000 circular mil oil-pipe cable construction consists of four compact segmental sectors, with two opposite segments insulated by two paper tapes and the assembly bound together with a 5-mil bronze binder tape intercalated with a paper tape; then metallized paper tapes and impregnated wood pulp paper insulation which, together, make a 315-mil wall; a 3-mil copper tape intercalated with cotton tape and one 102 by 204 mil copper D-shaped armor wire over-all, with a lay of 1.2 inches and making an outside diameter of 2.312 inches. The cable was mass-impregnated with a mineral base oil, having a viscosity of 2,600 Saybolt Universal seconds at 100 degrees Fahrenheit, and shipped in a 63-mil temporary lead sheath having a steel rip-wire to facilitate stripping.

The two respective constructions of 2,000,000-circular-mil gas-pipe cables were as follows:

1. 2,000,000-circular-mil compact segmental conductor with four segments, two opposite segments insulated by two paper tapes and the assembly bound together with a 5-mil bronze binder tape intercalated with an 8.5-mil manila paper tape; then 315 mils of paper insulation including metallized paper shielding tapes; a 4-mil copper tape intercalated with a 24-mil cotton tape and two 100 by 200 mil copper D-shaped armor wires over-all, equally spaced with a lay of 2.1 inches and making an outside diameter of 2.476 inches. The cable was mass-impregnated with a mineral base oil, having viscosity of 2,500 Saybolt Universal seconds at 100 degrees Fahrenheit, and shipped in a 90-mil temporary lead sheath having a steel rip-wire.

2. 2,000,000-circular-mil compact segmental conductor with four segments, three insulated with two paper tapes each and a 5-mil bronze binder tape over-all; then 315 mils of paper insulation including metallized paper shielding tapes; two 3-mil plain copper tapes without intercalated cotton and two 100 by 200 mil D-shaped copper armor wires over-all equally spaced with a lay of 2.1 inches and making an outside diameter of 2.412 inches. The cable was mass-impregnated with a synthetic oil having a viscosity of 140,000 Saybolt Universal seconds at 100 degrees Fahrenheit, and shipped in a 90-mil temporary lead sheath having a steel rip-wire.

Load Losses

In present designs of cables for pipe-type circuits, the proximity effect upon a-c conductor resistance substantially discounts the increase in load rating which accompanies a given increase in conductor size, particularly for sizes above 1,500,000 circular mils. Also, the parasitic energy losses in the binding tapes, skid wires, and in the pipe add materially to the heating effects.

Much remains to be learned concerning the sources and control of these various energy losses. For instance, low-voltage laboratory tests show the measured total energy losses at 880 amperes and 75 degrees centigrade conductor temperature to be in the order of 26 to 28 watts per foot for the two types of 2,000,000-circular-mil cables, as compared to 25 watts per foot observed on a similar test of the 1,500,000-circular-mil cable. Consideration of possible remedies for these unreasonably high losses suggests that the short-circuited sheath effects of metallic tapes and skid wires might be reduced appreciably by the use of high-resistance materials, also that there may be opportunity for drastic reductions in conductor losses as well.

The stranded segmental construction of these large conductors inherently transposes the strands in such a way that, if each strand were insulated, each should have essentially the same effective a-c impedance per transposition, and the current distribution should therefore be essentially uniform. This suggests that the controlled application of an insulating or high-resistance film on each of the copper strands of such conductors might almost eliminate proximity as a cause of extra a-c losses. If this reasoning can be confirmed by test, such an equalization of mutual reactance effects between strands would make 1,500,000-circular-mil conductors have approximately the same load rating as had been expected of the 2,000,000-circular-mil conductors in pipe.

It is important to realize that 25 watts per foot in a 6-inch pipe-type cable circuit are equal to the heat losses from a well designed 6-inch 150 pound-per-square-inch steam main. Cable engineers have learned to give steam mains the respect that is their due. Pipe-type circuit losses should have at least equal respect.

Load Ratings

The 1,500,000-circular-mil conductor size for oil pipe-type circuit was estimated to have essentially the same copper temperature at 880 amperes as that for 1,500,000-circular-mil oil-filled cable in duct. The larger 2,000,000-circular-mil conductor for high-pressure gas-pipe cable was specified to gain an expected lower copper temperature rise of 48 degrees centigrade ultimate, as compared to 50 degrees centigrade for oil-filled cable, and 52 degrees centigrade for the oil pipe-type cable. The comparative temperature rises are shown in Figure 2. Excessive losses in the gas-pipe cable designs have increased their ultimate temperature rises from the expected 48 to 55 degrees centigrade for the 26.5-watt construction and 58.5 degrees centigrade for the 28.4-watt construction. All of these calculations assume the earth to have a resistivity of 80 thermal ohm centimeters. A rather extensive program of tests begun in 1947 indicates that the average thermal resistivity of earth in Philadelphia is very nearly 75 thermal ohm centimeters; with a range from 34 minimum to 114 maximum in the characteristic clay subsoil, including seasonal variations.

Analysis of the thermal circuits involved was a large study in its own right The essentials of this work have been summarized in papers by J. H. Neher[1,2] and A. S. Mickley,[3] hence need not be reviewed here.

With but one exception, each of the pipe-type cable lines has a continuous service record of copper temperature, pipe temperature, ambient earth, and load. The copper temperature is obtained by adding the pipe temperature thermocouple output to that of a recently developed adjustable thermal circuit, calibrated to represent accurately the temperature rise from pipe to copper as determined by a test heat-run on the cable and pipe assembly.

Table I. Power Factor Tests on Oil Samples from Various 69-Kv Cable Lines

	Age in Years	Number of Samples	Per Cent Power Factor at 100° C		
			High	Low	Average
Low-pressure oil					
Chester-Upper Darby Line	6	60	7.83	0.48	2.91
200 pounds per square inch oil-pipe					
Plymouth Meeting Experimental Line	15*	3	2.21	1.66	1.99
South Delaware-Westmoreland Line	1½	12	1.00	0.265	0.58
Chester-Naamans Line	0	15	2.63	0.20	0.62

* In operation 12 years and de-energized three years, waiting changeover to high-temperature operation.

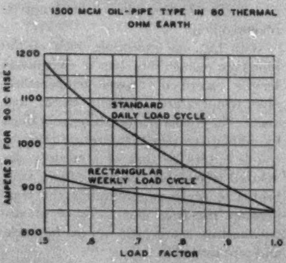
These particular pipe-type circuits were designed to operate under a load cycle which was recognized to place a severe limitation on load rating. From Figure 3 it will be seen that the 0.90 load factor is calculated to develop a 75 degree centigrade copper temperature, or 50 degree centigrade rise above no-load temperature, on 1,500,000 circular mil oil-pipe type cable at 860 to 900 amperes. The rectangular weekly load cycle is particularly severe, but characteristic of base load transmission operations for which these lines were designed. The standard daily load cycle and load factors in the range of 0.75 to 0.50 are representative of most other operations, for which the oil-pipe cable design of Figure 3 might have a 10 per cent to 35 per cent greater rating for the same copper temperature.

It was expected that the thermal resistivity of the earth would exceed 80 thermal ohm centimeters at some locations and in some seasons, as confirmed by subsequent tests. Therefore, the copper temperature in the design selected for the pipe-type cables was expected to exceed the normal operating limit of 75 degrees centigrade where such conditions prevail in small percentages of their length, but only if the operations at that particular season require the full-load rating under an adverse load cycle.

The maximum copper temperature recorded in nearly two years' operation of the oil-pipe cable line was 55.5 degrees centigrade in 44 thermal ohm centimeter earth at Southwark Station, or 31.5 degrees centigrade above earth ambient on August 28, 1948, when the load reached 980 amperes maximum at 0.655 load factor for the week. The maximum copper temperature recorded during 6 months' operation of the gas-pipe lines was 37 degrees centigrade at 892 amperes on December 12, 1948, or 25.5 degrees centigrade rise above earth ambient at 0.37 weekly load factor. From these observations it would appear that there is little risk of exceeding 75 degrees centigrade copper at the working load factors which have been well below the 0.90 specification for base load operations.

The sturdy qualities of high-pressure oil-pipe systems suggest it may be practical to accept the possibility of occasionally operating such cables at normal copper temperatures ranging up to 100 degrees centigrade. The occasions would be infrequent. The sheath crack problem is not present. Slight additional restraint against the somewhat greater expansion forces is provided readily. The only effect can be some life loss in scattered locations along the circuit. The experimental Oilostatic cable installation at Plymouth Meeting Substation is, therefore, about to be modified to operate in this higher temperature range.

Figure 3. Effect of load cycle on ampere rating for 1,500,000-circular-mil oil pipe-type installation in 80 thermal ohm centimeter earth



Connectors

The comparatively straight parallel lay of conductors in the pipe-type system which does not have the cable slack that is characteristic of duct and manhole installations, makes it imperative that the connector be designed to have substantial mechanical strength. The connectors for these pipe-type systems were designed to withstand about one-third the ultimate strength of the conductor. This is approximately twice the maximum stress which would accompany a possible 25 degree centigrade drop in conductor temperature after the connectors had been installed.

Figure 4 shows two designs of connectors, both of which have the required mechanical strength and ample electrical conductivity. Steel pin reinforcement was at first thought to be required. Simple radial compression has been found to be sufficient, but has the disadvantage that the press may require somewhat greater working space than can be provided conveniently in the joint casing assembly. The sleeves must be made from oxygen-free copper which will withstand deformation without cracking.

Insulation

The oil-pipe cable and about half of the gas-pipe cable had 315 mils of insulation mass-impregnated with mineral base oil having a viscosity of 2,500 to 3,000 Saybolt Universal seconds at 100 degrees fahrenheit. The remaining 2,000,000-circular-mil gas-pipe cable was mass-impregnated with a synthetic oil having a viscosity of 140,000 Saybolt Universal seconds at 100 degrees fahrenheit. The manufacturer of the synthetic oil made a substantial number of severe tests designed especially to determine whether the synthetic oil had the chemical, physical, and electrical stability required for this type of service. The results of these tests were very satisfactory and the synthetic oil was accepted.

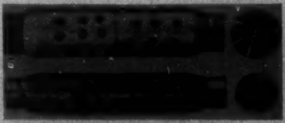


Figure 4. Types of connectors

(Above) 2,000,000-circular-mil connector, radial compression only

(Below) 1,500,000-circular-mil connector, circumferential compression with steel pin reinforcement

The gas-filled insulation was not expected to have the same rugged electrical qualities as high-pressure oil-filled cable insulation, although it had demonstrated sufficient strength at normal working pressures of 180 to 220 pounds per square inch. A disadvantage of the high-pressure gas-filled insulation is that the manufacturers are not willing to authorize operation at pressures below 100 pounds per square inch. This can become an im-

Table II. Typical High-Voltage-Time Test Data From Certified Test Reports on 69-Kv Cable

Test Voltage		Hours of Test Voltage Application					
		Low Pressure Oil Cables		200 Psi Gas Cables		200 Psi Oil Cables	
Kv	Avg. Volts per Mil	A	B	C	D	E	F
90	315	0	0	0	6	0	0
118	375	6	6	6	3	6	6
142	450	3	3	3	3	6	3
170	540	0.4	0.5	3	0.1	6	3
204	650	—	—	0.2	—	54	44.7 did not fail
204 to 354*	650 to 1,130*			—		9.1*	
Hours to breakdown		9.4	9.5	12.2	12.1	81.1	

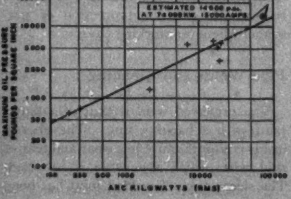
* The voltage was raised continuously at the rate of 20 per cent in three hours.

portant consideration in case a serious leak should occur. The high-pressure gas-filled stop joints were designed for 115 kv at 200 pounds per square inch, in order to have the same 60-cycle strength as the 69-kv cable at 50 pounds per square inch. The high-pressure oil-pipe cable system requires only that the minimum pressure be kept above atmospheric pressure.

Experience to date suggests that the oil in the high-pressure oil pipe-type systems has considerably more stability than the highly refined oil in low-pressure oil-filled cable. Recent 100 degrees centigrade power factor tests of typical oil samples are summarized in Table I. Power factor is but one evidence of oil changes with time and exposure. There are cases where values above 10 per cent at 100 degrees centigrade have been considered tolerable, but operators naturally would prefer to have oils which age with minimum evidences of change from their initial condition.

Typical high-voltage 60-cycle breakdown test data are summarized in Table II from Certified Test Reports on cable supplied for these lines. The endurance of the 200 pound per square inch oil pipe-type cable construction seems almost phenomenal, in comparison to low-pressure oil and 200 pounds per square inch gas which failed at approximately one-half the 1,130 volts per mil breakdown for the oil pipe-type cable. Test F was not carried to failure, because the 204-kv maximum output of the test set was inadequate to cause breakdown within a reasonable time.

Figure 5. Effect of arc energy on maximum oil pressure for cable faults in oil-filled pipe



Cable designers no doubt would be interested in more detailed review of the technical differences between the respective cable constructions used. From the operating point of view, however, there appears to be no reason to expect the 69-kv high-pressure gas-filled insulation to be any less satisfactory than oil-filled cable insulation; provided the inherent design limitations are observed.

Pressure Media

A few significant characteristics of oil and gas respectively, as pressure media, are summarized in Table III, where P is absolute pressure in pounds per square inch.

Table III

	Oil	Gas
Viscosity at 100 degrees Fahrenheit		
In Saybolt Universal seconds	850	
In pounds per foot seconds, absolute	0.115	0.0000123
Density, in pounds per cubic foot, at 0 degrees centigrade	58.7	0.0055 P
Thermal expansion coefficient ($a = dV/Vd\theta$), per degree centigrade	0.00068	0.0039
Bulk modulus of elasticity ($B = VdP/dV$), in pounds per square inch	210,000	1.4 P
Maximum pressure change with temperature (aB), in pounds per square inch, per degree centigrade	143	0.0055 P

Gas pressure is seen to be relatively insensitive to temperature changes, whereas oil pressure is so sensitive as to require automatic compensation. To compensate for a 30 degree centigrade temperature drop in the $6^5/_8$-inch pipe, for instance, requires supplying 30 gallons of oil for each 1,500-foot pipe section between semistop joints. The Philadelphia oil-pipe system designs provide for pressure control at each end of the line so as to permit keeping the pipe full of oil at all times, even though sectionalized, as by freezing in order to permit cutting the pipe for cable repairs. The line is supplied normally from one plant.

The instantaneous maximum transient pressure which can be attained in the compression medium during conductor faults is determined by the rate at which the energy of the fault can be dissipated by the accompanying pressure wave within the pipe. These pressures are over four times as great in oil as in gas, being approximately

$$p = KI(t/A)^{1/3} \text{ pounds per square inch} \quad (1)$$

where

K = a coefficient which accounts primarily for the elastic and inertia properties of the fluid, being nine for oil and approximately two for 200 pounds-per-square-inch gas
I = the fault current in amperes
t = paper insulation wall thickness in inches
A = square inches gross area enclosed by the pipe

Figure 5 summarizes the pressures observed on several tests in oil-filled pipe. The two tests for staged faults having less than 300 arc kilowatts were made in 1934 by the Pennsylvania Railroad on a sample of 132-kv oil pipe-type cable. The fault currents were 410 and 465 amperes, respectively. The six remaining tests were made by The Okonite-Callender Cable Company, Inc. in 1945 on a sample 15-kv oil pipe-type cable installation at fault currents ranging from 4,650 to 11,380 amperes. Readings of arc amperes and arc voltage gave the direct indication of arc kilowatts used as the basis for correlating these tests, indicating arc resistances in the range of 2 ohms per inch of insulation thickness at very light faults down to 1 ohm per inch at 10,000 amperes.

The transient hoop stress is independent of pipe diameter, since the maximum hoop stress in the pipe is proportional to the product of the diameter by the instantaneous maximum transient oil pressure and the latter is inversely proportional to the diameter. The duration of the transient maximum stresses is so short as to preclude cold flow or necking down the pipe wall. Consequently, the transient ultimate strength of the pipe wall approaches a limit approximately equal to the product of its conventional ultimate strength by the ratio of the original to the necked down cross-sectional area of the test specimen at the break. The steel in question tested 60,000 pound per square inch ultimate strength and had a 50 per cent neck-down under the conventional test, which indicated a

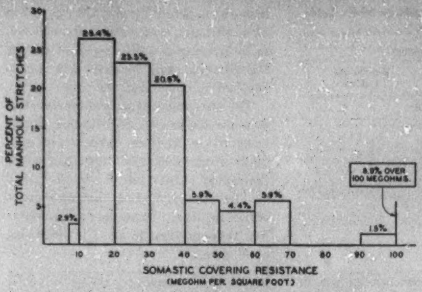


Figure 6. Somastic pipe covering insulation resistance for 90,000 feet of 6⅝-inch outside diameter pipe-type cable circuits in Philadelphia

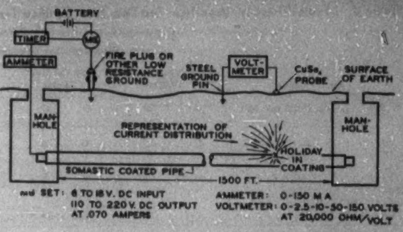

Figure 7. Method used for locating holidays in buried Somastic coated pipe

transient ultimate strength of 120,000 pounds per square inch maximum. Consequently, a 3/8-inch steel pipe wall was estimated to have just about the bursting strength required to contain a 15,000 ampere fault on 69-kv cable under the most adverse conditions.

Cable Failures

For an approximate appraisal of the probable failure record, it was assumed that oil pipe-type systems might have a record comparable to oil-filled cable which, in 2,307 cable-mile years of reported use from 1930 to 1942 inclusive, had experienced three cable failures and 13 joint failures. This amounted to 2.1 failures per 100 circuit-mile years for the three cable circuit designs considered. Examination of the physical relation between cable surfaces and the pipe wall suggested a probability that one-third of the failures would impinge upon and burn through the steel pipe wall having any practical thickness being considered.

It seemed extravagant to provide a 3/8-inch pipe wall and accept the additional energy losses in the hope that an occasional pipe burst might be thus avoided, with so low a failure rate and a probability that one-third of the failures would perforate the pipe at the point of failure in any event. The additional thickness could not be expected to have any practical effect upon life expectancy in exposures to corrosion or arc-burns. Hence, the 1/4-inch wall was preferred for oil as well as for gas.

Construction experience suggests that the simplest and least expensive fault repair procedure is to open the trench, freeze the oil, cut the pipe and make a buried-joint type of repair. The required parts and the construction specification are available for such use in case of need. Oil-contaminated earth can be replaced at little extra cost, if encountered. The alternative of replacing the three cables in a 1,500- or 2,000-foot cable section would almost certainly require more material, labor, and time. A comparable repair procedure also is provided for gas pipe-type cable failures.

Pipe Coating

All of the Philadelphia pipe-type circuits have a 7/16-inch wall of Somastic, Type II coating designed to maintain its integrity at temperatures up to 65 degrees centigrade, as needed for such construction. This coating is somewhat brittle at freezing temperatures, hence the location and repair of defects commonly known as holidays can be simplified considerably by avoiding winter construction schedules where practical.

The initial insulation resistance of this Somastic coating is above 10 megohms per square foot. Figure 6 summarizes the insulation resistance readings on 90,000 feet of pipe construction completed to date, as accepted after repairing known holidays.

Each length of the coated pipe is inspected above ground with a 40-kv spark test set constructed by this Company. The standard 20-kv test set did not have the strength found necessary to locate many pinholes, particularly in the pipe weld covering. The pipe is welded into sections up to 200 feet maximum length and laid or threaded into the trench, depending upon conditions imposed by obstructions, and the backfill is placed.

After each stretch of pipe is completed between manholes, a low-voltage insulation resistance test is made as a final check on the integrity of the pipe coating. This is done by applying an intermittent direct voltage of 100 or 200 from one end of the pipe to a nearby water pipe or driven ground.

The method of locating holidays is shown schematically in Figure 7. A holiday in the coating is located by moving a copper sulphate electrode along the ground surface at 3-foot intervals directly above the pipe and parallel to it. Experience has shown that larger intervals are impractical due to the fact that the sphere of influence about a small holiday is very limited. The electrode is connected through a high-resistance voltmeter, to a driven steel ground rod located 50 feet to 100 feet from the pipe. When the holiday is approached, the signal sent out by the automatic timer becomes discernible on the voltmeter, the extent of needle swing on the meter becoming greatest at a point directly over the holiday. The swings range from 0.05 volt to 0.5 volt depending on the size of the holiday, location of the copper sulphate cell and local earth resistivity. This method has located holidays which had passed inspection with a conventional 20-kv spark test set. The accuracy of location is usually within ±12 inches, even through concrete or granite block paving.

A recent check test on one 25,000-foot pipe circuit shows that the coating resistance still averages 1 megohm per square foot after two years of service. It has been found possible to keep the pipe at least 1/2-volt cathodic by proper bonding, with both ends solidly grounded. A driven ground connection is provided in each manhole and standard procedure requires its use for protection of personnel whenever working therein.

Pipe Welds and Cleaning

The preferred weld is that of a flared joint with a backing ring. The smooth inside contours cause less wear and tear of skid wires when the cable is installed. The sleeve-type of welded joint has been

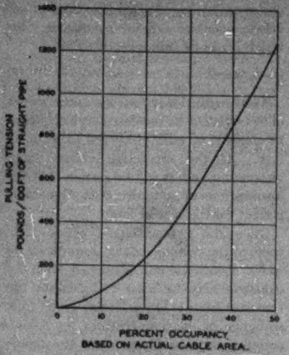

Figure 8. Cable pulling curve for straight sections of pipe-type cable installed in oil-lubricated pipe

used as an alternative, but is rougher and has an undesirable dirt accumulating pocket. Experiments with the use of a pneumatic internal expanding tool for aligning the pipe ends and temporarily backing the weld suggest that the method may considerably simplify fabrication and welding procedures. Each weld is proof-tested at 500 pounds per square inch, Somastic covered, and spark-tested.

Cleaning the inside of the pipe has been a problem now thought to have been solved by deferring the operation until just before the cable is installed. Each manhole-to-manhole section of pipe is then cleaned with a rotary wire brush tool, vacuum dried, and filled with dry nitrogen gas. The impracticability of preserving precleaned interior surfaces inviolate while storing, handling, and installing the pipe casts considerable doubt upon the integrity of such procedures. In fact, it is questionable whether practical precautions with the precleaning procedure will result in cleanliness comparable to the preferred alternative of cleaning in place.

Pulling Tensions

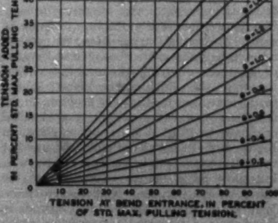
All manhole locations and related cable pulling lengths for the approximately 20 miles of pipe-type cable circuits installed to date, had to be established before any cable had been installed. It has since been found that somewhat longer cable pulling lengths are permissible. Using the percentage of total cable cross-section to internal area of the pipe as a measure of occupancy, the first two 1,500,000-circular-mil circuits occupied 41 per cent of their $6^{1}/_{8}$-inch inside-diameter pipes, the third 1,500,000 circular mil circuit occupied 45 per cent of its $5^{7}/_{8}$-inch inside-diameter pipe, and the 2,000,000-circular-mil circuit occupied 48 per cent of its $6^{1}/_{8}$-inch inside-diameter pipe. Forty per cent occupancy has been considered altogether reasonable, but the higher percentages required for the later installations were considerably beyond the limits of common practice. For instance, the circumscribing circle limit of three cables in a pipe is 65 per cent occupancy in the foregoing reference scale.

The $6^{1}/_{8}$-inch inside-diameter pipe was considered practically ideal for 1,500,000-circular-mil cable. For purposes of design, the maximum pulling tension is limited to the 10,000 pounds per square inch nominal elastic limit of soft drawn copper, with an assumption that one of the three conductors may be required to withstand as much as one-half of the total pulling tension.

Straight-away pulling tensions with properly lubricated pipe in sections without bends may be summarized for practical purposes as in Figure 8, in terms of percentage occupancy alone. The relationship has been found to be altogether dependable for 69-kv cable sizes ranging from 700,000 circular mils at 16 per cent occupancy to 2,000,000 circular mils at 48 per cent occupancy. The tensions shown in Figure 8 are about 15 per cent lower than were estimated from a review of published test data[4] on pulling tensions for smaller cables in duct.

The pulling tension added by a pipe-bend is determined predominantly by the cable tension at the entrance to the bend, the arc length of the bend and its radius. These relationships are summarized for convenient reference in Figure 9.

Figure 9. Tension added at pipe bends as determined by tension at bend entrance and the ratio θ of bend arc length to radius



Total pulling tension then can be computed readily in steps and the cutting length determined when the total reaches the maximum permissible pulling tension which, of course, includes the braking and other friction losses at the cable feed-in point, as well as the weight of cable in such vertical pipe sections as may be encountered.

For practical purposes the layout can be simplified materially by allowing approximately 15 per cent of the maximum permissible pulling tension to account for the numerous small bends to be found in nominal straight-away construction, and accounting specifically only for the major bends accompanying major deviations from straight pulls. This was the method used in selecting manhole locations for the 35,000-foot pipe line now about to be installed.

Pressure Controls

The pressure controls for these pipe-type systems were engineered by the respective cable manufacturers. The gas-pressure controls are extremely simple, involving little more than high-pressure gas bottles, a pressure reducing valve and a low-pressure alarm. The comparative incompressibility of oil, its specific gravity and high viscosity, however, require a comparatively intricate system of pumps, reservoirs, and automatic controls.

In the oil-pipe circuits, there is a semistop joint at each cable joint, with by-pass piping and automatic valves designed to reduce materially the rate of oil supply to any section in which the oil pressure drops below 75 pounds per square inch for any reason, as in case of a pipe break.

The system has appeared to work very well when supplying oil demands from a pump at one end of a circuit so long as its length is in the order of 4.5 miles and 18 semistop joints. Some additional field tests will be required to determine whether it is practical to increase the length appreciably without any special provisions.

For illustration of the general relationships involved, consider the conditions for oil flow through the distributed resistance in the main pipe and the lumped resistances of the by-pass pipe assemblies at the semistop joints, as actuated by thermal expansion of the oil in the main pipe.

The critical velocity for turbulence in viscous oil appears to be well beyond the thermal displacement velocities expected.

For nonturbulent flow in an unobstructed pipe, the friction loss is given by Poiseuille's law

$$\frac{dp}{dx}=(k/D)^2\mu v \text{ pounds per square inch per foot} \quad (2)$$

where k^2 is a constant, μ is the absolute viscosity of the oil, v is the average velocity, and D is the pipe diameter. The obstructions offered by the cables in the main pipe, and by the fittings and valves in the by-passes, suggest that $(k/D)^2$ be treated as a constant to be evaluated by test on the particular pipe in question.

To evaluate the pressure losses accompanying the heating or cooling of the oil requires expressing the average velocity of displacement in terms of the distance from the closed end of the pipe. In the main pipe, with oil having a thermal expansion coefficient of (1/1,500) per degree centigrade and undergoing an r degrees centigrade per second change in temperature, the average thermal displacement velocity at distance x from the closed end is $v_m=(rx/1{,}500)$ feet per second.

By direct substitution in equation 2 and integrating for values of x between the limits of 0 and nL, where n is the number of sections and L is the length per section, the total pressure loss in the main pipe is found to be

$$p_m=(k/D)_m^2\mu r n^2L^2/3{,}000 \text{ pounds per square inch} \quad (3)$$

The velocity of oil flow is inversely proportional to the fluid cross-section and, if c indicates the ratio of main to by-pass fluid cross-sections, the velocity in the by-pass is $v_b=(crx/1{,}500)$ feet per second. Hence, the pressure loss in the by-pass pipe of length b becomes

$$p_b=c(k/D)_b^2\mu rbx/1{,}500 \text{ pounds per square inch} \quad (4)$$

in which the values of x are successively L, $2L$, and $(n-1)\,L$ for the respective by-pass locations at L-feet intervals in the line, so that the sum of these by-pass pressure losses is

$$p_b=c(k/D)_b^2\mu rbnL(n-1)/3{,}000 \text{ pounds per square inch} \quad (5)$$

and the total pressure loss from equations 3 and 5 is

$$p=p_m+p_b=\mu r(nL)^2G/3{,}000 \text{ pounds per square inch} \quad (6)$$

where

$$G=\left(\frac{k}{D}\right)_m^2+\frac{bc}{L}\left(\frac{k}{D}\right)_b^2\left(1-\frac{1}{n}\right)$$

p = pressure change caused by oil temperature changes, in pounds per square inch
μ = absolute viscosity of the oil, in pounds per foot seconds
r = time rate of oil temperature change, in degrees centigrade per second
n = number of main pipe sections
L = average main pipe section lengths, in feet
b = average by-pass pipe lengths, in feet
c = ratio of main to by-pass pipe fluid cross-section
$(k/D)^2$ = a constant for the particular pipe section

It will be seen that the pressure loss is jointly proportional to the viscosity, the rate of change in temperature and the square of the total length of the line, since G in equation 6 rapidly approaches a constant value as n increases. It will be observed that the greatest cooling rates occur at the higher operating temperatures which reduce materially the viscosity of the oil and the effective friction head. The total effective head against which the pressure control system must work is the algebraic sum of the friction and gravity heads.

For a given line, the value of G in equation 6 can be determined readily by a test at constant oil temperature and viscosity μ_0. By bleeding oil from the far end of the pipe while the oil supply pump is in active service, a predetermined pressure drop p_0 may be held constant and the resulting velocity v_0 of oil flow may be observed by measuring the rate of oil delivery under these conditions, for which it can be shown readily that

$$G=p_0/\mu_0 v_0 nL \quad (7)$$

As a precautionary measure, the values of G, or $(k/D)^2$ as the case may be, should be checked at each of several rates of oil flow. If the respective values agree reasonably well, it will be certain that the assumption of nonturbulent flow was correct for the case at hand.

Once the precautionary check tests confirm the validity of the assumption on which equation 6 was developed, then the equation may be used to calculate the transient friction loss p for any given time sequence of oil temperatures by taking account of their effects upon the factor μr.

Conclusion

High-pressure gas pipe-type construction avoids certain familiar inconveniences inherent in treating and handling cable oils. It remains to be demonstrated, however, that the gas-filled insulation will earn for itself a record of dependability approaching that already established by oil for use at 69 kv and upward. Meanwhile, Philadelphia Electric Company's seven miles of high-pressure gas pipe-type circuits should contribute a fair share to the necessary experience record.

Discussion

Robert J. Wiseman (The Okonite Company, Passaic, N. J.): This paper reviews the many problems which faced us back in the early 1930's when we first introduced the high oil pressure pipe system, and the progress that has been made in design and installation procedure so that today we have a much better knowledge of its mechanical, physical, and electrical characteristics.

One of our big problems was the correct earth thermal resistivity to use when calculating the conductor size to carry the load. Should we follow the English practice of using 120 thermal ohm centimeters (net) or use a lower value as had been found by some of us when studying the problem? Fortunately, the Philadelphia Electric Company was willing to study the problem on the Oilostatic installation which was installed originally in 1932. The results as shown in Figure 1 of the paper not only told us what the effective earth thermal resistivity was, but gave us a chance to appreciate the shape of the transient temperature curve. We were able to use an empirical formula to calculate the transient temperature which checked the actual curve very nicely. Note that we obtained on this test as low as 60 thermal ohm centimeters, but to be conservative, we took a value of 80 for future calculations. This can easily cover any hot spots that may occur along a route. Any spots having higher values will probably be rare and of short length, and also actually exist for a very short time. It is not economically feasible to design a line for these isolated cases and the system can well handle them. The authors refer to this in the section on Load Ratings.

Although the authors state that the higher temperature rise for the 2,000,000-

circular-mil gas cable was due to the higher losses in the conductor over that for the 1,500,000-circular-mil oil cable, it also is a fact that the thermal resistance inside the pipe for the gas cable was about the same as for the oil cable, whereas it would have been lower if both systems had had the same thermal characteristics. We have made tests and found this to be so. As a result, we use a thermal resistivity for the insulation of 500 thermal ohms per centimeter for the Oilostatic (oil pressure) cable and 550 for a gas-pressure cable. For the pressure zone we have found we can get sufficiently accurate values of thermal resistance if we use $R_{th} = 1.60/D$ thermal ohms per foot for the Oilostatic cable and $R_{th} = 2.58/D$ thermal ohms per foot for a high gas-pressure cable where D is the diameter over the shielding tape on the single-conductor cable.

We are looking forward to the time when the authors will give us a progress report on the thermal operation of their lines.

We have no hesitancy in allowing the Oilostatic cable system to operate at 100 degrees centigrade conductor temperature under an emergency condition. We are wondering how closely we can approach this temperature for normal temperature. As far as insulation is concerned, thermal time tests indicate no physical or electrical deterioration when held at 100 degrees centigrade for at least three years, indicating at present, perhaps 85 or 90 degrees centigrade feasible. The limitation, as I view it, will be based on how much drying out of the soil around the pipe will occur. It may not be too great based on the ideas presented by A. S. Mickley.[1]

Reference is made to the modification in the experimental Oilostatic cable installation at Plymouth Meeting Substation to obtain a higher temperature range. The information given below may be of interest to those who are following the subject: An 800-foot section of the Oilostatic installation has three 400,000-circular-mil conductors in place of the 1,000,000-circular-mil conductor. With the contemplated load of 75 megavolt-amperes at 75 per cent load factor, we have estimated a pipe temperature of 59 degrees centigrade and a conductor temperature of 101 degrees centigrade, with an earth ambient temperature of 20 degrees centigrade. Will this pipe temperature cause drying out of the earth? Time will tell. It is expected that an emergency load of 103 megavolt-amperes may take place for several hours. If it follows the 75-megavolt-ampere load and the conductor has reached 101 degrees centigrade, then in two hours the conductor is estimated to reach 150 degrees centigrade and the pipe 72 degrees centigrade. We do not plan to let the conductor go over this temperature. We are looking forward to this study with great expectations.

Although it appears it is not necessary to use the steel pin reinforcing for connectors, we believe they are worthwhile as a further strengthening against excessive tensions if the cable goes to low temperatures.

We are interested in the authors stating that the gas-filled insulation was not expected to have the same rugged electrical qualities as high-pressure oil-filled insulation, shown in Table II of the paper. This brings up a point for discussion. If we are satisfied with the breakdown voltage obtainable with the gas-filled insulation, which is about the same as for low-pressure oil cables, then why not reduce the insulation thickness for high-pressure oil systems? We are ready to do so by 10 per cent and perhaps as much as 20 per cent. This also is in accord with the ideas advanced by Dr. L. Domenach.[2] We recognize that in some cases the impulse level of the insulation must be considered. However, Dr. Domenach has obtained some high impulse tests on his cable, partially due to using very thin tapes next to the conductor, but also I believe because of the high pressure that he uses.

There are several factors involved which influence the instantaneous pressure that is developed in case a short circuit takes place in a pipe system. For the gas type we have the formation of gas due to the burning of the insulation by the arc, and as the authors state, the pressure developed is not great because of the compressibility of the gas. In the case of the oil type, we have the formation of gas due to the arc burning oil and insulation, which creates a positive pressure and the stretching of the pipe, the absorption of gas by the oil and the propagation of the wave in both directions to the joints, all of which are negative, in that, they tend to hold down the pressure. The resultant pressure is not as large as one would expect. The authors show in Figure 5 of their paper the pressures that are liable to be expected. I would prefer to express it as a function of kilowatt seconds of energy as it is the latter which determines the amount of gas formed which causes the sudden pressure. Also in determining pipe thickness, we must keep in mind that it is the ability to withstand sudden pressures rather than a static pressure that is important.

In the beginning when setting up lengths of sections we believed it feasible to use 2,000-foot lengths. Conditions of installation showed 1,500 feet was a better average to take. We note that there is a trend toward longer lengths without getting excessive pulling tensions. I think this is good, but we must be careful in not going ahead too fast until data are collected showing what pulling tensions are found. It appears that 2,000-foot lengths are safe, and possibly 2,500 feet. I agree with the authors that percentage of occupancy is important, although I am more inclined to believe it is more important on the basis of allowable space for radial expansion of the cables, particularly when longer lengths of sections are used.

While pressure control of a gas system is relatively simple, it would appear that for an oil system such control is complicated. This is not true. It requires a storage tank for the oil supply, and since the oil changes in volume as its temperature changes, a pumping plant also is required to maintain the pressure. The superiority of the oil pressure system over the gas system justifies its extra pressure-control setup.

One of the problems that we have on an oil-pressure system is the building up of the pressure if the load is suddenly applied on a very long line when it is at a low temperature. Calculations have indicated, and actual tests have shown, that these pressures are not high enough to cause any damage to the system. Likewise when dropping load it is essential that the pump capacity be large enough to supply oil to the far end of the system and all restrictions to flow be kept to low values. Experience with the various installations that have been made has helped us to attain this end.

This paper should help weigh the evidence of the relative merits of the two systems as to their over-all design, installation, and operating characteristics.

2. Cables with Reduced Thickness of Insulant Under Pressure, Dr. L. Domenach. International Conference on Large High Voltage Electric Systems (Paris, France), June 1948.

R. W. Atkinson (General Cable Corporation, Bayonne, N. J.): The authors emphasize the undoubted desirability of reducing any unnecessary costs and complications during installation. It is helpful to consider several items involved in construction and to discuss the purpose of some of the refinements and the degree to which the means used are justified by the results.

1. The need for removal of the temporary sheath is disappearing with increasing acceptance of shipment of the cable without such a sheath.

2. One method of jointing produces a joint that is electrically as strong as the cable by virtually reproducing the mechanical and electrical equivalent of the factory applied insulation. Even where a joint can be made having a strength equal to the *specified* strength of the cable at lower cost or much more expeditiously, there seems to be grave doubt of the desirability of accepting anything that is not able to meet any tests which the cable actually can meet. In short, can a joint be acceptable if, on a type test, the joint fails and the cable does not fail? The answer to that question will have much to do with the direction of development of jointing.

3. Stop joints, complete or semistop, add much to the installation problem as compared to simple normal or nonstop joints. The suggestion toward reducing or eliminating these is noted. The experience at New Orleans with complete absence of stop joints helps to encourage that arrangement at least for high pressure oil-filled cables.

4. The difficulty involved in the production of high electrical strength of a joint is considerably increased if the connector greatly exceeds the conductor diameter. There has recently become available a connector which is satisfactory in conductivity and in mechanical strength and which is a little larger in diameter than the conductor. This connector materially reduces the cost and time required to produce a joint of high electrical strength as compared with earlier forms of solderless connectors which were significantly larger than the conductor.

5. In many of the existing high pressure oil systems, the pipe oil has been thoroughly degassed before it enters the system and means are taken to assure that it stays that way. This involves some degree of extra trouble and cost. In other systems, the oil is admitted under conditions which cause it to be gas-saturated at around atmospheric pressure. It should be recognized that this may result in a definite sacrifice in reference to the ability of the cable to be operated temporarily at pressures in the range of atmospheric. With the fully degassed oil operation at low pressure, when required, is

fully justified because this does not result in any tendency to form gas bubbles as would be the case where the oil does not remain fully degassed.

One wonders whether it is a significant handicap to the gas-pressure cable that it is undesirable for such a cable to be operated at pressures greatly under the normal values. Only a direct break in the pipe or end equipment need result in low pressures with gas whereas these and many other things, even a power failure to the supply pump may cause failure of oil pressure. In any event with gas pressure there is some evidence that temporary operation at low pressure may be found permissible. Indeed, some data have been found surprisingly favorable.

A word may be said here concerning pipe losses. These should be independent of the pipe thickness within the commercial range sizes. Due to skin effect in the pipe, only about the inner 1/16 inch plays a significant role in the losses due to the pipe. The remainder of the wall is pretty thoroughly screened from electrical current or magnetic field at the power frequency of 60 cycles.

It is of interest to note the close correlation between pulling tension and per cent occupancy of the duct, without any direct relation to the weight of the cable or size of the pipe. It will be of further interest to tie this in with previous data where the pulling tensions have been correlated with the weight, without reference to per cent of occupancy. It may be found that a still broader application of the data may be made by taking both into account than with either one alone.

W. Allistair Sinclair and **Francis M. Hull** (The Detroit Edison Company, Detroit, Mich.): The authors should be commended for their valuable contribution to the experience record of pipe-type cable. They state that because of the sturdy qualities of high-pressure oil-pipe systems it may be practical to accept the possibility of occasionally operating such cables at normal copper temperatures ranging up to 100 degrees centigrade. Sections of *SMD*-type high-pressure, gas-filled cable, having 600,000 circular-mil conductors insulated with both 600 mils of preimpregnated and mass-impregnated paper in a 7-inch outside diameter steel pipe have been operated at such temperatures on the Detroit Edison Company's 120-kv experimental line. The 700-foot cables have been operating with a potential of 69 kv between conductor and ground and the conductor temperatures have been maintained at approximately 100 degrees centigrade for 1,600 hours. These cables now are being subjected to further and more severe tests. They have been operated on a "12-hours on, 12-hours off" schedule for load current with loads up to 790 amperes per conductor for 310 days. High voltage to ground is maintained continuously. Power factor tests indicate no apprecciable deterioration of the insulation This schedule provides daily variations in conduetor temperatures of from 100 to 30 degres centigrade and constitutes a severed test of the ability of the cable to withstand rough usage.

It must be remembered, however, that theire is a limit to the number of watts which can be dissipated without encountering accumulative heating. Such a condition developed in January during the above cycling. The cables had been subjected to 70 days of cycling previous to the time that this condition developed. In seven days the shielding temperatures, at the end of each load period, increased 15 degrees. On each successive cycle the increase in temperature was rapidly becoming larger. During this interval the line was dissipating between 57 and 60 watts per foot.

At the start of the load period on the eighth day, the high voltage was removed but the temperature rise during the first six hours equalled that obtained during the previous 12-hour load period. The load was decreased from 770 to 500 amperes for the remaining six hours of the load period. The line was then left out of service for 36 hours during which time power-factor measurements were made. Since the results were of the magnitude expected, the line was placed back in operation. During the first load period, 500 amperes were applied at low voltage and the high voltage also was applied at the start of the load period of the second cycle. The load was increased on each successive cycle until on the sixth cycle the load was the same as that which existed at the time the runaway was detected. The cycling was then continued for 227 days without any long-time shutdowns. During this period there was no indication of a reoccurrence of the runaway condition.

Our new lines and terminal equipment, therefore, are being designed on the assumption that loads which will produce 100 degree centigrade copper temperature may be impressed ultimately.

Soldered-type, countersunk, copper connectors were used on our experimental and our first commercial lines. These connectors have a diameter the same as that of the cable conductor. Two cases of open circuits in joints have been encountered on the commercial line. Both of these open circuits occurred during periods that the line was out of service due to overhaul of the generator and, incidentally, during periods of the lowest ambient earth temperature.

Recently one of the joints on the experimental line was dismantled and it was found that the solder had been extruded at the end of the connectors. There also was some evidence that similar action had taken place at the center of the connector where the conductors butted. This particular joint had been subjected to 310 days of cycling load and it was possible that an open circuit would have occurred if the cycling had been continued.

Compression-type connectors were used on the line completed last year and is now our standard for pipe-type cable.

Somastic coating has been utilized on all the Detroit, commercial pipe-type circuits and the difficulties encountered were similar to those mentioned by the authors. It is interesting to note that their spark test voltage has been increased to 40 kv. However, it is not stated whether this is rms or peak voltage and where it is measured. In Detroit, each nominal 40-foot length of pipe is tested with a 20-kv rms voltage between points on the outside of the 1/2-inch covering and the pipe itself. This voltage is measured by means of sphere gaps. Each completed section of pipe between manholes is tested in a manner similar to that outlined in the paper.

Every reasonable effort is made to obtain a measured resistance (as accepted after repairing known holidays) from pipe to ground of not less than 10 megohms per square foot of the outside surface of the pipe. Table I of the discussion is a comparison of the insulation resistance readings on 65,000 feet of pipe construction completed during 1948 with the results shown in Figure 6 of the paper. This table shows the Detroit results to be higher than those obtained in Philadelphia. This might indicate the need for a specification covering the testing of the Somastic covering so that all construction would be tested on the same basis and directly comparable.

Table I

Somastic Covering-Resistance, Megohms Per Square Foot	Per cent of Total Manhole Stretches	
	Philadelphia	Detroit
0–10	2.9	3.4
10–20	26.4	26.7
20–30	23.5	10.0
30–40	20.6	3.3
40–50	5.9	10.0
50–60	4.4	13.3
60–70	5.9	3.3
70–80		
80–90		
90–100	1.5	6.7
Over 100	8.9	23.3

G. B. Shanklin (General Electric Company, Schenectady, N. Y.): The paper by A. H. Kidder and G. S. Van Antwerp represents a very useful contribution to the pipe cable art, where additional knowledge and experience of this kind is still badly needed.

The manufacturers and users of cable of this type are all working on the problem either individually or in co-operation. During the course of our work findings and conclusions on some aspects of the problem are not in full accord with those presented by the authors and it might be well to discuss these briefly.

The authors conclude that for the same loading and temperature rise pipe cable requires the same conductor size as single-conductor oil-filled cable in underground ducts. This same thought has been expressed by others on previous occasions, but according to all of the information we have been able to obtain the equivalent conductor size for pipe cable is from 25 to 50 per cent larger than that of single-conductor oil-filled in ducts. This is particularly true for the heavier loads and larger conductor sizes, such as the 1,500,000-circular-mil conductor mentioned in the paper. Like many of the present differences related to pipe cable, the a-c losses assumed in the calculations are undoubtedly involved. Recent studies of such losses show that the armour losses and the steel pipe losses are somewhat higher than previously assumed. On the other hand, losses in lead sheathed cable are already well established.

The authors also conclude that, other things being equal, a high pressure gas-filled pipe cable conductor should be at least 33 per cent larger than an equivalent oil-filled pipe cable conductor for the same loading. All of the test data we have been able to obtain would not indicate that this is so. As far as thermal characteristics are concerned, there is only a slight advantage in favor of oil-filled pipe cable and for all practical purposes the conductor sizes are the same for both. Here again the variable a-c losses found in pipe cable and the, as yet, lack of full control of these losses, may have influenced the authors' conclusion.

Table I of the paper gives measured power factor values on samples of oil withdrawn from low pressure oil-filled cable and high pressure oil-filled pipe cable after several years of service. Based on these measurements the authors conclude that the oil used in the pipe cable has greater temperature aging stability. We have made a number of aging tests on both types of oil and without exception the thinner oil used in oil-filled cable has shown greater aging stability. The primary reason for this is that this thinner oil was especially designed and developed as an insulating oil, while that now used in pipe cable was actually borrowed from the lubrication field. It undoubtedly has sufficient stability for all practical purposes, but this stability is definitely not equal to that of the other oil mentioned. It is true that, all other things being equal, aging stability of oils increases with viscosity, but it does not prove to be so in this case. The higher power factor of the thinner oil in Table I is actually due to the much more limited volume of oil in the self-contained type of cable and the large surface exposure to copper in the conductor core. Copper, of course, is a very active catalyzer of oil.

C. T. Hatcher (Consolidated Edison Company of New York, Inc., New York, N. Y.): The authors are to be complimented on presenting a comprehensive picture of the problems involved in selecting cables for a high-capacity tie system. Any utility engineer, who has been in the position to make a decision regarding the type and size of cable to be installed to meet a prescribed loading condition, knows some of the troubles which are experienced before the cable construction is decided upon.

The effect of binding tapes, skid wires, and pipe all add to the losses in the cables. This has been thoroughly shown in the paper presented by L. Meyerhoff and G. S. Eager.[1] Considerable work now is being carried on in regard to these losses and it is hoped that in the future the selection of cables will be somewhat easier since sound data will be available.

Limited test data to date on oil from our pipe systems indicates that the oil is stable. Sufficient data has not been collected to make a direct comparison between oil from low-pressure oil-filled cables and oil from the pipe systems.

Limited experience appears to confirm the authors' conclusion that the simplest and least expensive fault repair procedure is to open the trench, freeze the oil, cut the pipe, and change a relatively short length of cable.

I do not agree with the authors that cleaning the inside of the pipe at a coating plant and maintaining the pipe in a clean condition is an impractical procedure. Methods have been developed for providing a satisfactory internal coating at a central location and plugging the pipes during shipment so that the pipe is received in a clean and satisfactory condition. Receipt of pipe in this condition speeds up the installation and restoration of street conditions. Any cleaning of inside pipe scale in the field would apparently require time and it is questionable if the scale could be removed completely from a manhole-to-manhole section.

I also question the authors' statement that the length of a pipe system should be limited to $4^{1}/_{3}$ miles when supplied with one pumping plant. The length of a system to be supplied depends upon the restriction in the line, namely, by-pass connections at the semistop joints, and we have found that this situation can be controlled by installing larger by-pass pipe. At the present time we are installing a line approximately ten miles in length with approximately 20 semistop joint locations with a supply from only one end. Test data on existing lines indicates that this will be satisfactory.

A. H. Kidder: The authors appreciate deeply the interest shown by the several discussers and particularly their comments concerning points which merit additional consideration.

Mr. Atkinson has stated accurately on several points, a position which is almost in complete accord with our own. We were as surprised as he, to find that our maximum pulling tensions could be summarized entirely in terms of per cent occupancy. In fact, we obtained a better correlation on this basis than when we attempted to deal in terms of weight, friction coefficient, and assumed conductor configuration within the pipe. We think one of the difficulties with the latter method is that conductor configuration is unpredictable.

We shared Mr. Hatcher's preference for precleaning the pipe, until we were convinced that adequate cleaning could be accomplished at lower cost after the pipe had been installed. We have consistently avoided the use of any internal pipe coating, because we were uncertain of its compatibility with the oil, particularly when locally carbonized as during welding operations.

Our analysis of one test on Mr. Shanklin's 2,000,000-circular-mil pipe-type cable construction as supplied for one of our projects, suggests that its unusual high losses are attributable entirely to certain unexpected effects of hitherto commendable precaution against oxidation of the conductor strands during the course of cable manufacture and treatment.

Judged in terms of the tests reported in the AIEE paper by L. Meyerhoff and G. S. Eager, Jr.[1] however, it is now apparent that Mr. Shanklin's 2,000,000-circular-mil cable in pipe has approximately the same a-c conductivity as others have reason to expect from 1,600,000 circular mils. I therefore shall continue to disagree with Mr. Shanklin's often repeated claim that oversize conductors are required.

The 2,000,000-circular-mil conductor size for the gas pipe system was specified with Mr. Shanklin's consent in what we considered a reasonable attempt to avoid operating the gas-filled insulation at temperatures above 75 degrees centigrade in locations where the thermal resistivity of the earth might exceed 80 thermal ohm centimeters. In this case the 2,000,000-circular-mil conductor in high pressure gas has approximately the same temperature rise per watt of a-c losses as does the 1,500,000 cable in an oil-filled pipe. We shared his unwillingness to permit gas-filled insulation to operate at temperatures above 75 degrees centigrade and, consequently, specified the larger copper size in order to reduce the watts losses.

Mr. Shanklin's explanation of the lower measured power factor on samples of oil withdrawn from high-pressure oil-pipe cable is enlightening. We had thought the oil to have greater temperature aging stability. It is now apparent that the superior performance of the oil in pipe is in part, at least, attributable to the reduced exposure to copper as a catalyst—a factor which can be controlled even in oil-filled cable designs, as by coating the copper strands with a tin or lead alloy.

The experience of W. A. Sinclair and F. M. Hull with 100 degree centigrade operation on *SMD* type high-pressure gas-filled cable, is an antidote for our discomfiture in the knowledge that our gas-pipe cable has 15 to 23 per cent greater a-c resistance than had been expected. We are very much interested in their report of accumulative heating, with losses in the order of 57 to 60 watts per foot.

The spark test voltage in Philadelphia is measured only by means of point-to-point gaps in air. For testing the 7/16-inch Somastic coating on the pipe, the voltage is increased until the spark will jump a 3/4-inch gap setting. For testing the 1-inch thick molded Somastic covering over pipe welds, the voltage is adjusted to spark across a $1^{1}/_{2}$-inch gap setting. This is admittedly a much less accurate voltage measurement than that obtained by the use of sphere gaps as reported by Mr. Sinclair and Mr. Hull.

As Dr. Wiseman points out, a greater 60-cycle breakdown strength of insulation in high-pressure oil suggests considering a reduction in insulation thickness provided satisfactory impulse strength can be maintained.

Our analysis of the transient pressures summarized in Figure 5 of the paper should, perhaps, be amplified somewhat in the light of Dr. Wiseman's comment that kilowatt-seconds may be a factor. We found the pressures to be proportional to the square root of the arc-kilowatts, and apparently independent of arcing-time. This confirmed our mathematical analysis which had indicated that the maximum transient pressure should be a natural function of the maximum rate of fault energy input as measured in Btu per second or kilowatts. We, therefore, prefer to deal in terms of arc-kilowatts rather than in terms of kilowatt-seconds.

Dynamic Braking Control of D-C Series Motors—Experimental Study of Speed-Torque Curves

G. W. HEUMANN
MEMBER AIEE

Synopsis: This paper presents the results of tests to determine the speed-torque characteristics of a d-c series motor driving a crane hoist. Direct readings of speed and torque during dynamic braking lowering operation were taken for various values of resistance in the motor circuit branches. A comparison between test data and calculated performance, using a conventional method of calculation, indicates that calculation obtains performance curves which are sufficiently accurate to forecast the performance of a practical crane hoist controller.

WHEN a series motor is used to retard an overhauling load by dynamic braking, motor power circuits are represented by Figure 1. The series field and the armature are connected in parallel. In series with the series field, there is a block of resistance R_F which includes the internal resistance of the series field and the series brake.

In series with the armature, there is a block of resistance R_A which includes the internal resistance of the armature and commutating field, and the equivalent brush drop resistance. A series resistance R_S is connected in series with both the armature and the field. R_S includes the resistance of the power leads between the point of constant line voltage V and the motor.

For many years, control circuit designers have used a method of calculating speed-torque curves which was described by A. A. Merrill.[1] Expressing motor performance quantities in per unit, speed and torque can be calculated by the following equations.

$$S=\frac{E}{K} \tag{1}$$

$$T=KI_A \tag{2}$$

where

S = speed in per unit of rated speed
T = torque in per unit of rated torque
E = electromotive force in per unit of normal generated motor electromotive force at rated torque and rated speed
I_A = armature current in per unit of rated full-load current
K = a factor, expressed in per unit, which is a function of field current and armature current

Factor K (equivalent to the commonly used terms "torque per ampere" and "volts per revolution per minute") is determined from motor test data. For motoring operation, it is permissible to consider K as a function of field current only, as the effect of armature current is negligible. When the motor is operating as a generator, retarding an overhauling load, the effect of armature current on K must be considered.[2] Knowing K from motor test records, an analysis of the motor circuit can be made, using Ohm's law and calculating currents and voltages in the various branches of the motor circuit.[3] Knowing motor electromotive force, field current, and armature current for each assumed operating point, speed and torque can be calculated using equations 1 and 2.

Test Set-up

To check the accuracy of the aforesaid method of calculating dynamic braking motor performance, a series of tests was conducted on an experimental hoist. Figure 2 is a view of the motor driving the hoist, which is beyond the wall to the right. An electromagnetic torque meter, rated 1,000 pounds-feet, which is described elsewhere,[4] is mounted between the motor coupling and the hoist coupling. It reads the torque transmitted between motor and hoist shafts directly in pounds-feet. On the left side of the motor are the series brake and a d-c tachometer generator for reading motor speed on a voltmeter calibrated in revolutions per minute.

Test Motor

Tests were made with a series motor whose nameplate data included the following: C01830, 50 horsepower, 30 minutes, 550 rpm, 230 volts. All quanti-

G. W. Heumann is in the Control Engineering Divisions, Apparatus Department, General Electric Company, Schenectady, N. Y.

The author wishes to acknowledge the assistance given by K. A. Andrew and J. A. Hepperlen in obtaining the experimental data used in this paper.

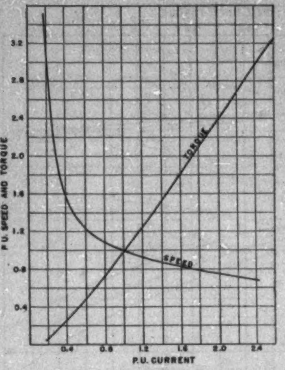

Figure 3. Per unit speed and torque versus current of test motor

ties relating to motor performance in this paper are given in per unit. The base quantities are as follows:

Base torque, 482 pound-feet
Base speed, 550 rpm
Base current, 185 amperes
Base voltage, 206 volts
Base resistance, 1.113 ohms

Internal resistances of the motor at rated temperature rise, expressed in per unit, are

Armature plus commutating field	0.079
Series field	0.037
Total	0.116

The fundamental characteristic of the motor is plotted in Figure 3. These data were taken from conventional test records of a motor of the same type as the test motor.

Curves for K as a function of field current and armature current are given in Figure 4. These data were obtained from special tests on a motor of the same type during which the motor was driving a load, or was driven as a generator, with various amounts of resistance in series with the field and the armature. Values of K were calculated from the measurements of torque, speed, and currents in the motor branch circuits. The dashed curve in the motoring quadrant has been calculated from Figure 3. This K curve obtains satisfactory calculated speed-torque curves for motoring operation.

Effect of Losses

Equation 2 for the calculation of torque is correct rigorously only when T is the internal developed torque of the motor, and K were determined on the same basis. The torque delivered at the shaft differs from the developed torque by the losses. Values of K, given in Figure 4, include losses, as they were determined experimentally from the shaft torque at each test point. When K is then used to calculate torque and speed for a different operating condition, losses are different. The question then arises what error is introduced in the calculations by the neglect of motor losses.

Core loss, friction, and windage are a function of speed, and core loss is also a function of field current. The sum of these losses, taken from test data of a motor of the same type as the test motor, expressed as per unit torque loss, is plotted in Figure 5 as a function of speed for various values of field current. The loss curves are straight lines. Friction and core loss change linearly with speed, except for very low speeds. Windage changes with the second power of speed, but as the test motor is totally enclosed, the windage loss is very small. At two per unit speed it is less than 0.001 per unit torque, thus its effect is negligible.

The dashed curve in Figure 5 represents losses with the motor operating as a straight series motor according to Figure 3. Thus, the dashed curve represents the losses included in the K factors of the dashed curve in Figure 4. During actual motor operation low speeds are associated with high-field currents and high speeds with low-field currents. Hence, Figure 5 indicates that neglecting core loss, friction, and windage introduces an error in the torque calculations of less than 0.01 per unit.

The foregoing discussion does not include the "load" or "stray" losses which are generally taken as a fraction of the core loss. Experience with similar motors, which has been set down in an AIEE Standard[6] indicates that the "load" losses vary between 22 per cent of the core loss at light load and 65 per cent at twice normal load. The error introduced in the torque calculations is less than 0.01 per unit, so that neglecting all losses introduces an error of less than 0.02 per unit in the calculated torque.

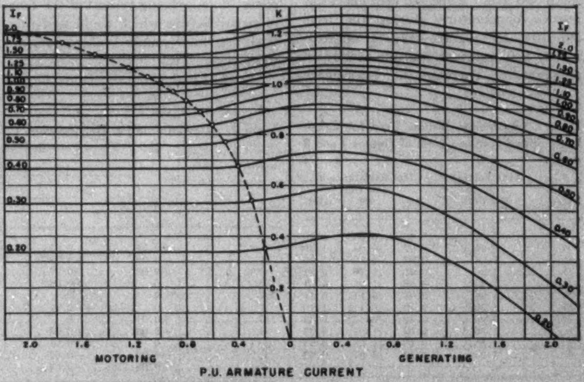
Effect of Resistor Heating

Cast grid resistors, which are applied on many crane installations, were used during the tests forming the subject of this paper. Cast grids have a comparatively high temperature coefficient. The increase in resistance is of the order of 7 per cent for each 100 degree centigrade rise. Since their permissible temperature rise is 350 degrees centigrade, it is necessary to consider the resultant increase in resistance when calculating speed-torque curves for installation.

To illustrate the effect of resistance changes due to heating, two sets of calculated dynamic braking curves are given in Figure 6, which are typical for low-speed and high-speed lowering points of a crane hoist controller. For each speed point, three curves are plotted. Curves (A) were calculated with the resistor at room temperature, and curves (B) and (C) were calculated with all resistance values increased 10 and 20 per cent respectively.

In the region of low speeds, which are

Figure 4. K-factor of test motor



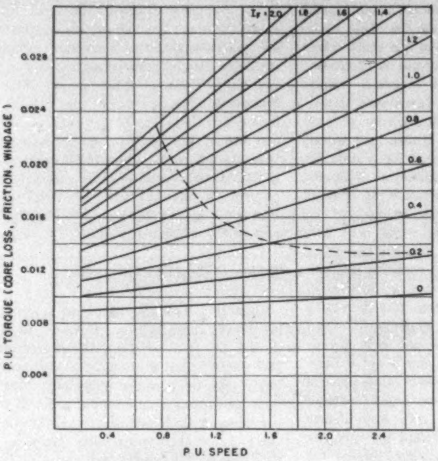


Figure 5. Core loss, friction, and windage of test motor

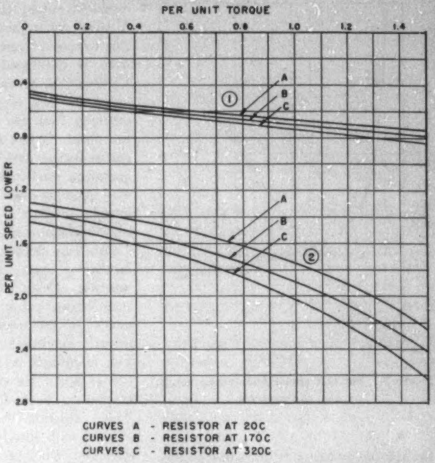

Figure 6. Typical calculated lowering speed-torque curves indicating effect of cast grid resistor heating

associated with high-field currents, the difference between cold and hot resistance has only a minor effect. However, in the region of high speeds, in which the field current is below normal current, a decrease in field current due to resistor heating results in a considerable decrease in factor K and a consequent rise in speed. For the tests on the experimental hoist, the cold resistance of each resistor section was measured by a bridge. The hoist was operated prior to each test until resistor temperature became stabilized and consistent speed and torque readings were obtained for each resistor setup and load. Repeated spot checks of resistor temperatures during the tests indicated an average rise of approximately 300 degrees centigrade over room temperature. Therefore the performance curves, with which test results are compared in the following paragraphs, were calculated with hot resistances, 20 per cent higher than measured cold values.

Test Data

The results of tests on a number of typical dynamic braking circuits are plotted in Figures 7 and 8. The resistances connected in the motor circuit branches, including internal motor resistance, are shown in Table I. These values were used to calculate the curves. The heavy dots are the test readings. The curves shown are not associated with any particular design of crane hoist controller. They were selected from a large number of test data as being typical of the range of circuit setups which could find practical use on dynamic braking lowering controllers.

Figures 7 and 8 contain the readings of 64 individual tests. In Table II the deviations between calculated and tested values are tabulated as per-unit differential in speed. Positive deviation means that measured speed is higher than calculated speed. The occurrence of the deviations is plotted in Figure 9, each dot representing the occurrence of a deviation in Table II.

The majority of the deviations occur within a band of ±0.03 per unit. It is generally accepted by control engineers that calculated speed-torque curves may reasonably be within 0.05 per unit deviation from actual speed. Therefore, the correspondence between calculated curves and test data is quite satisfactory for practical purposes.

The calculated speed-torque curves

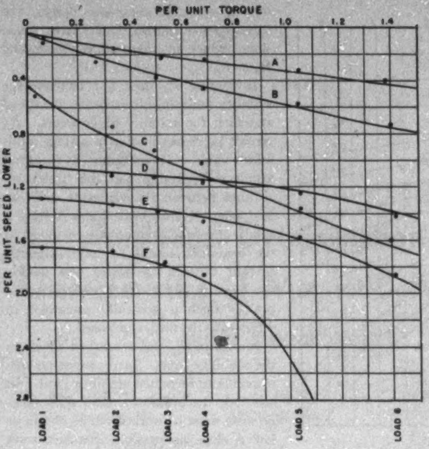

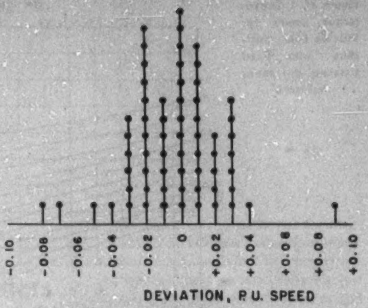

Figure 7(left). Comparison of calculated speed-torque curves and test readings

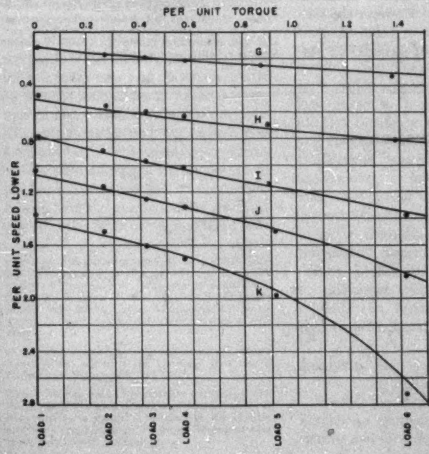
Tests A to F

Figure 9 (above). Occurrence of deviation between calculated and measured speeds

give a good indication of the load at which instability may occur. Consider curve (F) in Figure 7. With that circuit it was possible to lower load 4, which corresponds to approximately 0.70 per unit motor torque or rated load on an average crane hoist. When it was attempted to lower load 5, corresponding to approximately 1.15 per unit motor torque or 165 per cent load on the hook, it was impossible to obtain stable speed readings, as would be expected from the shape of curve (F).

Figure 8. Comparison of calculated speed-torque curves and test readings

Tests G to K

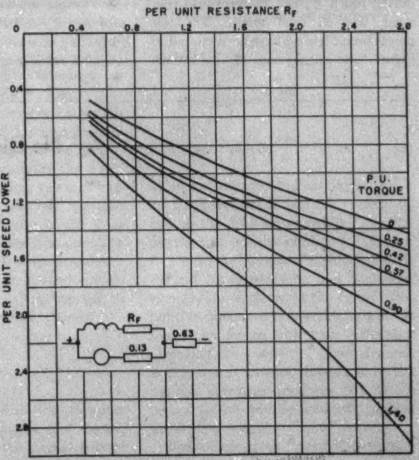


By comparison, refer to curve (K), Figure 8. This curve has considerably less slope in the range between 2.60 and 2.80 per unit speed, and it was possible to lower load 6, corresponding to approximately twice rated hook load, at stable speed. Part of the improved performance on curve (K) is due to reduction in no-load speed by using somewhat lower resistance in the field circuit, and part is due to increase in series resistance, the beneficial effect of which had been pointed out in a previous paper.[3]

Application to Hoist Controller Design

In the design of a d-c dynamic braking crane hoist controller, the first step is to select the speed-torque curves it is desired to realize on the various controller points. Good controller design should obtain as uniform a spacing as possible of no-load and full-load speeds between controller points. The speed-torque curve on the

Figure 10. Speed versus field resistance with fixed armature and series resistance



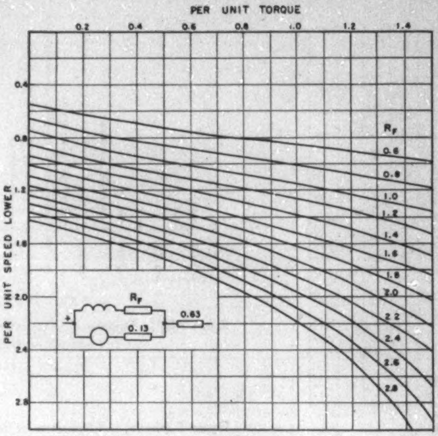


Figure 11. Speed-torque curves for variable field resistance with fixed armature and series resistance

final controller point should obtain as high no-load and full-load speeds as practicable, and still provide stable operation under overload.

In the range of high lowering speeds, control is essentially by inserting resistance in the motor field circuit. The amount of field weakening which can be safely employed limits the maximum speed for which the controller can be designed.

Figures 10 and 11 illustrate how the results of comparatively few tests can be utilized as an aid in controller design. As an example, consider tests H, I, J, and K, during which R_A and R_S were held constant, and R_F was varied. The test points from Figure 8 have been plotted in Figure 10 as speed versus R_F, for various values of torque. From this figure the speed-torque curves of Figure 11 have been drawn, giving speed versus torque for various values of R_F. This figure indicates the range of speed control which can be obtained by selecting various values of R_F. It also gives an approximate indication of the variation in speed due to resistor heating, as the effect of changes in R_F is large compared with changes in R_A and R_S.

An ideal crane hoist controller would have as little change as possible between no-load and full-load speed on each controller point. Theoretically, the flattest speed-torque curves would be obtained with zero R_A and R_S. However the stability limit of such curves would occur at too low a value of motor torque.[2] To obtain a workable controller design, the speed-torque curves must have some slope, which is increased by increasing R_A or R_S.

Increasing R_A does not increase the stability limit, it only increases the speed at which the stability limit occurs. R_A cannot be reduced below a certain minimum value. It contains the internal armature resistance and the trolley resistance between the armature and the controller. It may be desirable to leave a small amount of external resistance in the armature circuit to force sufficient current through the series field during acceleration, to insure that the series brake, which is generally connected in series with the field, is released.

Increasing R_S has a marked effect on the stability limit. Increased slope corresponds to increased stability limit. In selecting the proper value of R_S a compromise must be worked out to obtain as low a slope as possible, commensurate with sufficiently high stability limit. Any increase in no-load speed and any reduction in R_S reduce the torque at which unstable operation is to be expected.

Analytical Determination of Characteristics of Magnetic Amplifiers with Feedback

D. W. VER PLANCK
MEMBER AIEE

L. A. FINZI
ASSOCIATE AIEE

D. C. BEAUMARIAGE
STUDENT MEMBER AIEE

Synopsis: An analytical method is developed for predetermining the steady-state characteristics of magnetic amplifiers with feedback. The magnetization curve is expressed in a convenient functional form and analytical relations among the direct control current, alternating output current and applied alternating voltage are derived for two different feed-back circuits. Magnetic amplifiers without feedback are included as limiting cases. Simultaneous conduction of the rectifiers which occurs in feed-back circuits during portions of the cycle is taken into account and explained. Experimental checks confirm the soundness of the analysis throughout.

A MAGNETIC amplifier consists of interlinked electric and saturable magnetic circuits arranged so that a small amount of direct current controls the reactance of an a-c circuit.[1,2,3] Thus the a-c power to a load may be regulated by a much smaller power in the d-c control circuit. Amplifiers of greatest sensitivity usually involve self excitation or feedback.[4,5,6,7] The steady-state theory of magnetic amplifiers without feedback has been established and means for predetermining the characteristics are available.[8,9] The addition of feedback, however, greatly complicates the analysis and published theories are either only qualitative[8] or if quantitative, require semigraphical procedures for their application.[10] The purpose here is to give a quantitative theory of the steady-state operation of magnetic amplifiers with feedback which permits analytical predetermination of their characteristics.

While the theory is general, it is presented by showing its application to a particular circuit. Some results of similar analyses for other cases are given.

Self Feed-Back Circuit

The circuit chosen for illustration is shown in Figure 1. It comprises two identical saturable cores, each having a d-c control winding N_1 and an a-c load winding N_2. The control windings are connected in series with a d-c source. The load windings are connected through identical rectifiers *a* and *b* to an a-c source and load as shown. An increase of control current, which saturates the cores, has the effect of increasing the load current. Because of the rectifiers, the load current links the cores alternately, so as to add to the bias already introduced by the control current, and thus feedback occurs. In distinction from other circuits no additional windings are needed to produce the regeneration; hence the term "self feedback."

Analysis

Briefly, the method is first to apply Kirchhoff's voltage law to the electric circuits and solve for the magnetic fluxes in the two cores; then to use the magnetization curve of the material expressed in analytical form to find the corresponding mmf's; next to use Ampere's law to relate the magnetomotive forces and currents; and finally to solve for the currents. This procedure is facilitated by the following simplifications:

1. Steady-state conditions exist.
2. The load is replaced by a short circuit so that a sinusoidal voltage is impressed directly on the amplifier terminals.
3. The voltage impressed on the control circuit is constant and its source has no impedance to harmonic currents.
4. Winding resistances are very small though not neglected entirely.
5. Leakage fluxes are neglected, and the flux density is uniform throughout each separate core.
6. Eddy currents and hysteresis are neglected and the magnetic flux density—magnetizing intensity relationship is given by the normal magnetization curve of the core material.
7. Rectifiers have infinite resistance in the reverse direction and a constant, but very small, resistance in the forward direction.

Application of Kirchhoff's voltage laws, to the circuit of Figure 1 with the load replaced by a short circuit gives

$$E_{dc}=2R_1i_1+N_1\left(\frac{d\phi_\alpha}{dt}+\frac{d\phi_\beta}{dt}\right) \tag{1}$$

$$E_m\cos\omega t=R_2i_2+N_2\frac{d\phi_\alpha}{dt}+V_a \tag{2}$$

$$E_m\cos\omega t=R_2i_3-N_2\frac{d\phi_\beta}{dt}+V_b \tag{3}$$

V_a is the voltage drop across rectifier *a* in the direction of positive current i_2; and V_b the drop across rectifier *b* in the direction of positive current i_3. R_1 and R_2 are the resistances of each of the coils N_1 and N_2 respectively, and the other symbols are as shown in the figure. The positive directions of currents and fluxes have been chosen arbitrarily. The sign preceding the number of turns of a coil is negative if current through it in the positive direction produces flux in its core opposite to the assumed positive direction of flux.

The voltage drops V_a and V_b determine

Paper 49-139, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer General Meeting, Swampscott, Mass., June 20–24, 1949. Manuscript submitted March 21, 1949; made available for printing May 3, 1949.

D. W. Ver Planck, L. A. Finzi and D. C. Beaumariage are all with the Carnegie Institute of Technology, Pittsburgh, Pa.

This work was done in part under a contract with the Office of Naval Research, and in part by D. C. Beaumariage in partial fulfillment of the requirements for the degree of Doctor of Science at Carnegie Institute of Technology.

the operation of the rectifiers as follows:

$$V_a>0, \quad i_2>0, \quad V_a=i_2R_r \tag{4}$$

$$V_a\leqq 0, \quad i_2=0 \tag{5}$$

$$V_b\geqq 0, \quad i_3=0 \tag{6}$$

$$V_b<0, \quad i_3<0, \quad V_b=i_3R_r \tag{7}$$

where R_r is the forward resistance of each rectifier, assumed constant.

Consideration of the circuit and the foregoing equations shows the possibility of three conditions in each a-c cycle as follows:

> Rectifier *a* conducts and *b* does not. This is described by equations 4 and 6 and is termed a ***positive*** conduction period.
>
> Rectifier *b* conducts and *a* does not, as described by equations 5 and 7. This is called a ***negative*** conduction period.
>
> Both rectifiers conduct in accordance with equations 4 and 7. This is commutation.

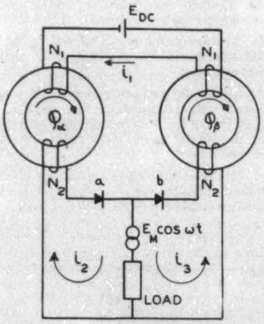

Figure 1. Magnetic amplifier with self feedback

The fluxes in the two cores are found for each of these periods by simultaneous solution of the appropriate ones of the voltage equations 1, 2, and 3 assuming that the resistance, drops, and consequently E_{dc}, are negligible. The flux densities in the cores, B_α and B_β respectively, are then found by dividing each flux by the core area A. For each period the result is the same, namely

$$B_\alpha=B_m \sin \omega t+B_0 \tag{8}$$

$$B_\beta=-B_m \sin \omega t+B_0 \tag{9}$$

where $B_m=E_m/N_2\omega A$. For each period a constant of integration arises, which can be shown to be the same for all periods and both cores, and equal to the average flux density. This quantity, identified by B_0, is as yet undetermined. For the commutation period only two of the three voltage equations available are needed to determine the flux densities; the third equation is utilized later.

The field intensities required in the cores are related to the flux densities through the magnetic characteristic of the material, assumed here to be the normal magnetization curve. This functional relationship has been represented analytically in several ways, for example by straight line segments,[11] the sum of a linear and a high odd powered term,[9] and the hyperbolic sine.[12] For the present purpose, a more satisfactory empirical expression is

$$H=U \sinh uB+vB \tag{10}$$

where U, u, and v are constants dependent on the shape of the magnetization curve. Using this form it was possible to fit the measured points to within the accuracy of the magnetic measurements for hypernik and silicon steel.

Substitution of equations 8 and 9 into equation 10 results in

$$H_\alpha=H_0+H_1 \sin \omega t+H_2 \cos 2\omega t+ H_3 \sin 3\omega t+H_4 \cos 4\omega t+\ldots \tag{11}$$

$$H_\beta=H_0-H_1 \sin \omega t+H_2 \cos 2\omega t- H_3 \sin 3\omega t+H_4 \cos 4\omega t-\ldots \tag{12}$$

where the coefficients of the series are in terms of modified Bessel functions of the first kind[13,14] as shown in Table I. If expressions other than equation 10 are used to represent the magnetization curve, equations 11 and 12 still apply but the formulas for the coefficients are not those in Table I. For instance if equation 10 is replaced by the sum of two hyperbolic sines, each harmonic coefficient has two terms each involving modified Bessel functions. A finite power series[15] instead of equation 10, gives coefficients which are polynomials in B_m and B_0. These other representations fit the magnetization curve of the material studied just as well as equation 10 and lead to equally good over-all checks, but they are less convenient mathematically.

Application of Ampere's law to each of the magnetic circuits relates the currents to the field intensities. Thus

$$N_1i_1+N_2i_2=LH_\alpha \tag{13}$$

$$N_1i_1-N_2i_3=LH_\beta \tag{14}$$

where L is the mean length of path for either core.

In the positive and negative conduction periods i_3 and i_2 are respectively equal to zero, and equations 13 and 14 suffice to determine expressions for the remaining two currents. With the aid of equations 11 and 12 the currents in these two periods are then expressed in terms of the harmonic components of field intensity as shown in Table II.

During commutation, however, all three currents exist simultaneously and a third equation is required for their determination. This is obtained by manipulation of the voltage equations 1, 2, 3, 4, and 7 so as to eliminate the time rates of change of flux but without ignoring the resistance drop terms as was done earlier. The resulting equation with equations 13 and 14 then leads to the expressions for the currents shown at the bottom of Table II. Here

$$k'=\left(\frac{R_2+R_r}{R_1}\right)\left(\frac{N_1}{N_2}\right)^2 \tag{15}$$

and

$$I_1=\frac{E_{dc}}{2R_1} \tag{16}$$

Although expressions for the currents in all periods of the cycle have been established, the times of transition between the periods have not been determined, nor is a relationship known connecting B_0, the time average of flux density, and I_1, the time average of control current. To break into the determination of these remaining unknowns the following significant facts are noted from a study of the expressions in Table II:

1. The output current (i_2+i_3) is given by the same expression throughout the cycle and passes through zero at $\omega t=0, \pi, 2\pi \ldots\ldots$ as indicated in Figure 2.
2. The expressions for the control current are such as to result in the symmetries about $\omega t=0, \pi, 2\pi \ldots\ldots$ and about $\omega t=\frac{\pi}{2}, \frac{3\pi}{2} \ldots\ldots$ indicated in Figure 2.

From this it follows that the times of transition between periods can be expressed in terms of a single angle σ as shown in Figure 2.

The angle of transition σ is determined by the voltage of equations 4 through 7. For instance at $\omega t=\sigma$, that is at the end of the commutation period (in which both i_2 and i_3 were flowing), just before positive conduction, i_3 and V_b are just reaching zero. Inserting these conditions in equations 1, 2, and 3 with $V_a=i_2R_r$ and eliminating the time rates of

Table I. Coefficients of Magnetomotive Force Harmonics

$H_0=U\mathrm{I}_0(uB_m) \sinh uB_0+vB_0$
$H_1=2U\mathrm{I}_1(uB_m) \cosh uB_0+vB_m$
$H_2=-2U\mathrm{I}_2(uB_m) \sinh uB_0$
$H_3=-2U\mathrm{I}_3(uB_m) \cosh uB_0$
$H_4=2U\mathrm{I}_4(uB_m) \sinh uB_0$
$H_5=2U\mathrm{I}_5(uB_m) \cosh uB_0$

$\mathrm{I}_n(x)$ is the modified Bessel function of the first kind.[13,14]

change of flux results in the relation between i_1 and i_2 which must hold at this instant. Then replacing i_1 and i_2 with their values for the commutation period as given in Table II results in the following equation connecting σ and N_1I_1

$$N_1I_1=L[(H_0+H_2\cos 2\sigma+\ldots)-(1+k')(H_1\sin\sigma+H_3\sin 3\sigma+\ldots)] \quad (17)$$

Consideration of the voltage conditions at the other transition times ($\omega t=\pi-\sigma$, $\omega t=\pi+\sigma$, and $\omega t=2\pi-\sigma$) in each case leads to this same relationship between σ and N_1I_1.

Another independent relation between N_1I_1 and σ is obtained by expressing the time average control current as

$$I_1=\frac{1}{2\pi}\int_0^{2\pi} i_1 d(\omega t) \quad (18)$$

using the expressions for i_1 given in Table II and integrating each between the proper limits. This results in

$$N_1I_1=LH_0-\frac{2L}{\pi(1+k')-2\sigma}\times\left[\left(\frac{H_2}{2}\sin 2\sigma+\frac{H_4}{4}\sin 4\sigma+\ldots\ldots\right)+(1+k')\times\left(H_1\cos\sigma+\frac{H_3}{3}\cos 3\sigma+\ldots\ldots\right)\right] \quad (19)$$

Elimination of N_1I_1 between equations 17 and 19 gives an expression from which σ may be determined if B_0 and B_m (which determine the H's) are known. To facilitate computation harmonic terms above the second order usually may be dropped without serious error. Doing this and making a number of transformations gives

$$\tan\sigma-\frac{1}{\frac{\pi}{2}(1+k')-\sigma}=\frac{1}{\tan\sigma+\frac{H_1}{H_2}(1+k')\sec\sigma} \quad (20)$$

The steps in determining the characteristics of a given magnetic amplifier with self feedback may now be summarized as follows:

1. Adjust the constants of equation 10 to fit the magnetization curve of the core material.
2. Calculate B_m for the applied alternating voltage desired.
3. Assume a value of B_0.
4. Use Table I to determine the harmonic coefficients H_n.
5. Use equation 20 to determine the angle of transition σ.
6. Calculate N_1I_1 from either equation 17 or 19 and use the other as a check on σ.
7. Calculate instantaneous currents using the expressions in Table II.

If the rectified average value of load current is desired, it may be calculated immediately following step 4 from

$$(i_2+i_3)_{\text{rectified average}}=\frac{4L}{\pi N_2}\left[H_1+\frac{H_3}{3}+\ldots\right] \quad (21)$$

If the rectifiers are omitted from the circuit under discussion, Figure 1, a familiar nonfeed-back magnetic amplifier with parallel load coils results. The foregoing analysis applies to this case also, if R_r is set equal to zero and the expressions in Table II for the commutation period are taken to apply throughout the cycle. The angle of transition σ has no meaning in this case. Integration of the expression for i_1 over the whole cycle leads to the result that $N_1I_1=LH_0$. The load current is given by equation 21 without modification.

Experimental Checks

Experiments were performed to check the validity of the assumptions made in the preceding analysis. For this, two shell-type hypernik cores with mean lengths of path of 7.12 inches and cross-sectional areas of 0.656 square inches were used.

A first set of experiments was directed to check the analytical predetermination of the average value of the alternating flux density B_0 as a function of B_m and of the control ampere-turns N_1I_1. For this, the amplifier with no feedback (Figure 1 with rectifiers omitted) was used. B_0 was measured by means of a fluxmeter inserted in an exploring circuit so as to eliminate odd harmonics of induced current through the fluxmeter coil. The results are shown in Figure 3. The calculated curves are found using the formulas $B_m=E_m/N_2A\omega$ and $N_1I_1=LH_0$ obtaining H_0 from Table 1 for assumed values of B_0. In these experiments $N_1=N_2=2{,}000$ turns, $R_1=115$ ohms, $R_r=100$ ohms, and the frequency of the a-c power source was 60 cycles per second. The curve for $B_m=0$ is the measured normal magnetization curve and for this case the approximation of equation 10 agrees within the accuracy of the magnetic measurements but is not plotted.

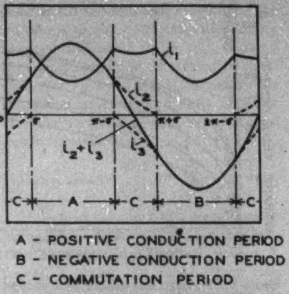

Figure 2. Representative current waveforms for magnetic amplifier with self feedback

A second set of experiments was made to check the analytical predetermination of the steady-state no-load characteristics of magnetic amplifiers with self feedback. Typical results are shown in Figure 4.

Figure 5 is typical of many comparisons of calculated instantaneous currents with oscillograms. It constitutes direct evidence of the phenomena of commutation or simultaneous conduction of the rectifiers.

Finally the effect of inserting a load was checked experimentally. It was found under conditions of equal control current (average value) and equal load current (rectified average value) that the

Table II. Instantaneous Currents in Self Feed-back Circuit

Period	Current
Positive	$i_1=\frac{L}{N_1}[(H_0+H_2\cos 2\omega t+\ldots)-(H_1\sin\omega t+H_3\sin 3\omega t+\ldots)]$ $i_L=i_2+i_3=\frac{2L}{N_2}\times[H_1\sin\omega t+H_3\sin 3\omega t+\ldots]$ $i_3=0$
Negative	$i_1=\frac{L}{N_1}[(H_0+H_2\cos 2\omega t+\ldots)+(H_1\sin\omega t+H_3\sin 3\omega t+\ldots)]$ $i_2=0$ $i_L=i_2+i_3=\frac{2L}{N_2}\times[H_1\sin\omega t+H_3\sin 3\omega t+\ldots]$
Commutation	$i_1=\frac{1}{N_1(1+k')}\times[k'L(H_0+H_2\cos 2\omega t+\ldots)+N_1I_1]$ $i_2=\frac{L}{N_2}[H_1\sin\omega t+H_3\sin 3\omega t+\ldots]+\frac{1}{N_2(1+k')}\times[L(H_0+H_2\cos 2\omega t+\ldots)-N_1I_1]$ $i_3=\frac{L}{N_2}(H_1\sin\omega t+H_3\sin 3\omega t+\ldots]-\frac{1}{N_2(1+k')}\times[L(H_0+H_2\cos 2\omega t+\ldots)-N_1I_1]$ $i_2+i_3=\frac{2L}{N_2}\times[H_1\sin\omega t+H_3\sin 3\omega t+\ldots]$

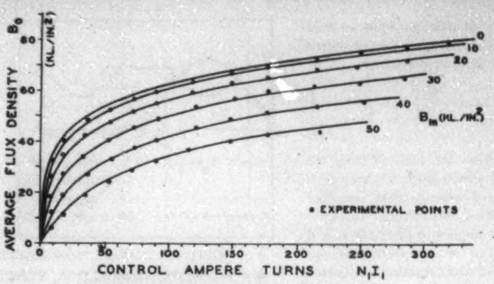

Figure 3. Average flux density as a function of average control ampere-turns and maximum alternating flux density

The upper curve is the measured normal magnetization curve of the material and the other curves are calculated

rms voltage drop across the amplifier terminals was substantially unaffected by the presence of resistance loads, even when the drop across the load was as high as 420 volts and that across the amplifier 140 volts. Moreover the current wave forms and the angle of commutation were not significantly altered by the load.

Physical Interpretation

It is to be emphasized at the outset that simultaneous conduction of the rectifiers is not caused by imperfections, for in the analysis the rectifiers have been assumed to have infinite backward resistance. To clarify this phenomenon of commutation, a consideration of the harmonic currents required for excitation is helpful.

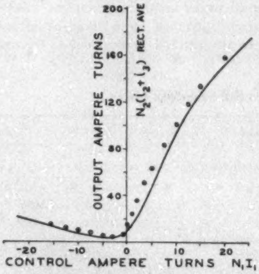

Figure 4. Characteristic of magnetic amplifier with self feedback

The curve is calculated, the points are measured experimentally. Core material as for Figure 3

$E_m=198$v, $\omega=2\pi 60$, $N_1=500$ turns, $N_2=4000$ turns, $R_1=31.5$ ohms, $R_2=240$ ohms, $R_r=50$ ohms

With the assumption of very small circuit resistances the fluxes must vary sinusoidally. That the flux in each core separately must vary sinusoidally in spite of the action of the rectifiers is a consequence of the coupling afforded by the control circuit. The displacement of the sinusoids of flux density, described by equations 8 and 9, results in part from the direct current in the control circuit, and requires magnetomotive forces having both odd and even harmonics as shown in equations 11 and 12.

Odd Harmonics of Magnetomotive Force

The odd harmonics of magnetomotive force, as shown by equations 11 and 12, have opposite signs in the two cores. When both rectifiers are conducting, the circuits and windings are so balanced that these odd harmonics can be produced only by identical components in the currents i_2 and i_3, see Table II, and these components can flow only through the a-c source. This occurs throughout the cycle in amplifiers without feedback. If, however, one rectifier is nonconducting, the current in the a-c winding of the core on that side is zero and the necessary odd harmonic components of magnetomotive force there have to be produced by current in the control circuit. But such a current in the control circuit produces odd harmonics of magnetomotive force of the wrong sign in the other core; hence the corresponding components of current in the load winding on that core must be double the former value. It will be seen that these conclusions agree with Table II.

Even Harmonics of Magnetomotive Force

The required even harmonics of magnetomotive force have the same signs in the two cores and therefore can be pro-

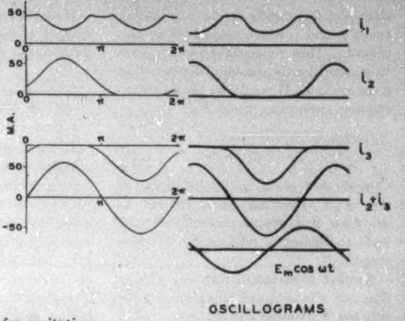

Figure 5. Calculated instantaneous currents (left) compared with oscillograms for the same conditions as Figure 4 and $N_1I_1=17$

The calculated curves are plotted to scales determined by the oscillograph sensitivity

duced by components of current i_1 or by components of currents i_2 and i_3 of equal magnitude but opposite signs. If the windings had zero resistance and there were no rectifiers the distribution of these components of current would be indeterminate.

Since the windings necessarily have resistance, voltages of corresponding harmonic frequencies have to be generated to balance the resistance drops which necessitate deviations from the initially assumed sinusoidal variation of the fluxes. These deviations are neglected in deriving equations 8, 9, 11, and 12, since the resistance drops are usually quite small in comparison with the impressed voltage, but it is recognized that small voltages of higher frequencies in fact must be induced in each winding to overcome the resistance drops. In the absence of rectifiers the currents which provide the needed even harmonics of magnetomotive force divide between the control winding and the external loop of the a-c windings in the inverse ratio of the resistances if the turns are equal, or in general in accordance with the factor k' defined by equation 15.

The rectifiers in no way alter the need for even harmonic components of magnetomotive force to sustain the displaced sinusoids of flux, but they do affect the way in which the currents to produce these magnetomotive forces are distributed between the control circuit and the external loop of the a-c windings. If either rectifier alone is conducting, the necessary component currents can flow only in the control circuit, the other possible path being interrupted. Consideration of the voltage relations shows, however, that as time goes on with one rectifier conducting there comes a moment when the voltage drop across the other rectifier passes through zero in the direction to cause conduction. Then for an interval both rectifiers conduct and the components of current which produce even harmonics of magnetomotive force divide between the two possible paths in accordance with the factor k' as they would with no rectifiers present. This condition persists until the current through the first rectifier drops to zero when conduction ceases and the second path for even harmonics is again interrupted.

External Feed-back Circuit

Another magnetic amplifier circuit providing feedback is shown in Figure 6. Here the feedback is obtained by rectifying the load current and passing it through a set of coils N_4 connected so that their magnetomotive forces reinforce those of the control coils N_1. The term external feedback is used to describe this circuit because coils external to the corresponding nonfeed-back circuit are required. The steps in analyzing the external feed-back circuit are similar to those for the self feed-back circuit and so only the important differences in the results will be indicated here.

Again it is found that there are three conditions in each a-c cycle.

1. A positive period when only the pair of rectifiers *aa* conducts and the feed-back windings N_4 are connected in series with the load windings N_2.
2. A negative period when only rectifiers *bb* conduct and the feed-back windings are again connected in series with the load windings but in opposite sense.
3. Commutation periods when all four rectifiers conduct simultaneously thus short circuiting the feed-back windings while the load windings alone support the impressed a-c voltage.

From voltage equations it is found that equations 8 and 9, and consequently equations 11 and 12, also apply to this case except that here $B_m=E_m/2N_2\omega A$.

Application of Ampere's law to the magnetic circuits leads to the expressions for the currents shown in Table III. Here I_1 is as given by equation 16, and

$$k''=\left(\frac{2R_4+R_r}{2R_1}\right)\left(\frac{N_1}{N_4}\right)^2 \tag{22}$$

where R_1 and R_4 are the resistances of single coils N_1 and N_4 respectively, and R_r is the forward resistance of a single rectifier. The factor k'' is analogous to k' defined by equation 15 and relates to the division of currents necessary to produce even harmonics of magnetomotive force between the two possible paths, in this case the control circuit and the short circuit through the feed-back coils when all rectifiers are conducting at once.

As in the self-feed-back case, the times of transition between the periods in each cycle may be expressed in terms of a single angle σ. Again two relations are found connecting σ and the average control excitation N_1I_1, one arising from consideration of rectifier voltage drops at the instants of transition, and the other from averaging the control current over the cycle. These relations are respectively

$$N_1I_1=L\left[(H_0+H_2\cos 2\sigma+\ldots)-\frac{N_4}{N_2}\times (1+k'')(H_1\sin\sigma+H_3\sin 3\sigma+\ldots.)\right] \tag{23}$$

$$N_1I_1=LH_0-\frac{2L}{\pi(1+k'')-2\sigma}\times \left[\left(\frac{H_2}{2}\sin 2\sigma+\frac{H_4}{4}\sin 4\sigma+\ldots.\right)+\frac{N_4}{N_1}\times (1+k'')\left(H_1\cos\sigma+\frac{H_3}{3}\cos 3\sigma+\ldots.\right)\right] \tag{24}$$

Eliminating N_1I_1 from these and dropping harmonics beyond the second results in

$$\tan\sigma-\frac{1}{\frac{\pi}{2}(1+k'')-\sigma} =\frac{1}{\tan\sigma+\frac{N_4}{N_2}\frac{H_1}{H_2}(1+k'')\sec\sigma} \tag{25}$$

Summarizing, the procedure for determining the characteristics of a magnetic amplifier with external feedback is the same as for self-feedback except that the transition angle σ is calculated using equation 25 instead of 20, N_1I_1 is found from equations 23 or 24 instead of equations 17 or 19, and Table III is used for the instantaneous currents instead of Table II. The rectified average value of load current is given by

$$(i_2)_{\text{rectified average}}=\frac{2L}{\pi N_2}\left[H_1+\frac{H_3}{3}+\ldots.\right] \tag{26}$$

If the feed-back turns N_4 are reduced to zero, Figure 6 becomes the familiar nonfeed-back circuit with load coils connected in series. In this limiting case, the instantaneous currents i_1 and i_2 are given by the expressions in Table III for the positive or negative period which become identical for $N_4=0$. The angle of transition σ in this case becomes zero and averaging the control current over the cycle gives $N_1I_1=LH_0$.

Comparison of Self and External Feedback

The expressions for instantaneous control and output currents in Table III for the external feed-back amplifier with series-connected a-c windings, Figure 6, become identical with the corresponding expressions in Table II for the self-feedback amplifier, Figure 1, if the comparison between the two is established as follows: equal core dimensions and materials; equal control windings and control currents; equal source voltages and a-c volts per turn; equal weights of copper for the a-c windings; and if it is further assumed for the external feed-back amplifier that the feedback and a-c windings have the same number of turns ($N_4=N_2$), mean lengths, and copper weights (which implies the availability of space for the feed-back winding). Under the terms of this comparison the total copper losses

Table III. Instantaneous Currents in External Feed-back Circuit

Period	Current
Positive.....	$i_1=\frac{L}{N_1}[(H_0+H_2\cos 2\omega t+\ldots)-\frac{N_4}{N_2}(H_1\sin\omega t+H_3\sin 3\omega t+\ldots)]$ $i_2=\frac{L}{N_2}[H_1\sin\omega t+H_3\sin 3\omega t+\ldots]$ $i_4=i_2$
Negative....	$i_1=\frac{L}{N_1}[(H_0+H_2\cos 2\omega t+\ldots)+\frac{N_4}{N_2}(H_1\sin\omega t+H\ \sin 3\omega t+\ldots)]$ $i_2=\frac{L}{N_2}[H_1\sin\omega t+H_3\sin 3\omega t+\ldots]$ $i_4=-i_2$
Commutation	$i_1=\frac{1}{N_1(1+k'')}\times[k''L(H_0+H_2\cos 2\omega t+\ldots)+N_1I_1]$ $i_2=\frac{L}{N_2}[H_1\sin\omega t+H_3\sin 3\omega t+\ldots]$ $i_4=\frac{1}{N_4(1+k'')}\times[L(H_0+H_2\cos 2\omega t+\ldots)-N_1I_1]$

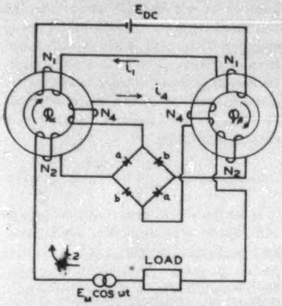

Figure 6. Magnetic amplifier with external feedback

are the same for both amplifiers. Thus the amplifier with self-feedback is superior to that with external feedback in that it gives identical performance with less material. It is to be noted, however, that the self feed-back circuit is less flexible in that there is no way to vary the amount of feedback as can be done by adjusting the number of turns N_4 in the external feed-back circuit.

Conclusions

An analytical predetermination of the no-load steady-state characteristic of magnetic amplifiers has been made possible in terms of design data and the properties of the core material. The operation of the magnetic amplifier depends basically on the fact that there is an average value of flux density and a superimposed alternating flux density; thus it appeared logical to develop expressions for the currents in the various circuits as functions of the two independent variables B_0 and B_m. Experimental checks agree closely with the results of calculation for a number of circuits with and without feedback using hypernik and silicon steel cores.

The analysis established here considers amplifiers with zero load impedance. This apparent limitation has the advantage of avoiding excessive analytical difficulty and eliminates the immediate need for considering the load impedance as a further variable. It is recognized that the presence of a load may alter the assumption of purely sinusoidal variation of core fluxes. An iterative process, initiated from the results of the present analysis appears possible, if needed, to study the true influence of a general load impedance. There is evidence however that such refinement may not be necessary. It is already customary to use experimentally-obtained no-load characteristics[3,4,16] of the type calculated here in the treatment of loaded amplifiers without feedback.[17,18] The work reported here indicates that the same procedures, based on conventional a-c circuit analysis, apparently also can be applied to feedback circuits.

No Discussion

The Logic of Relay Circuits

WM. KEISTER
NONMEMBER AIEE

MODERN telephone switching systems of the common control type such as the crossbar system, employ relay circuits which perform much the same actions as a human operator in setting up the connections for a telephone call. These relay circuits respond in an appropriate manner to signals of various types. They receive information in the form of a telephone directory number, evaluate it, locate suitable groups of trunks and paths through an interconnecting network of switches and from these groups choose a set of idle elements and connect them together for a telephone call. These telephone switching control circuits perform logical actions, and the design of such circuits is primarily an exercise in rigorous logic. The problem is usually one of producing specific effects in response to certain causes. Electric apparatus is merely a convenient means of detecting the causes and bringing about the desired effects.

A circuit designer in discussing the action of a relay circuit will often use such words as "tell," "remember," "know," and "choose;" words which are applied normally to rational mental actions and yet express with surprising accuracy the nature of actions performed in automatic switching systems. The actions, however, are not a result of independent thinking on the part of the units, but are more in the nature of automatic response to control signals. The designer has analyzed the situations which may occur, determined what shall be done for each one, and built into the control mechanisms a means for recognizing the situations and reacting accordingly. The machine then "knows" what to do for a definite set of circumstances and is able to analyze a combination of preconceived conditions and produce for each condition a result which agrees with the precise pattern of logic laid out by the designer.

The ways in which complex relay circuits such as those of telephone switching systems perform logical actions cannot be explained easily, without considerable discussion of technical details of the systems in which they are used. However a general discussion of a few fundamental ideas with simple examples will illustrate that the design of these circuits is basically a process of constructing a relay analogy of a chain of logical reasoning in which bits of information are received and correlated and suitable actions taken.

Contact Networks

A pair of mating contacts for making or breaking an electric circuit which will be called simply a contact, is basically a 2-valued device. At any given time it is either open or closed. In this respect a contact corresponds to an "open or shut" proposition in logic which can be demonstrated under given conditions to be either false or true. A 2-terminal network of contacts is similar to a single contact in that it is either open or closed for any given set of conditions. By 2-terminal network is meant a network consisting of individual contacts connected together in a configuration which provides but two entry points. Such networks connected in a circuit with a battery can control the actions of relays in a complex control circuit. A 2-terminal network corresponds to a proposition whose truth or falsity depends on the truth or falsity of a number of individual propositions, the individual propositions corresponding to the individual contacts in the network. The development of a contact network to perform a certain function is an exercise in logic of the kind which is used in building up a proof that a certain statement is true or false by demonstrating that a number of other statements are true or false. Furthermore, the arrangement of the individual contacts in the network is similar to the way the various statements are related to prove that the given statement is true or false.

Two-terminal contact networks correspond to propositions which may sometimes be true and at other times false and not to propositions which are basically true. (These would prove to be short circuits.) For example, the proposition that "the 5:30 train will arrive on time" may be either true or false and will depend on the truth of a number of other propositions such as (*a*) "it left the last station on time," and (*b*) "the track is blocked." The original proposition may be true if proposition (*a*) is true and (*b*) is false. The use of a false proposition to prove the truth of another corresponds to the use of break contacts on a relay which close a circuit path only when the relay is not operated. A relay may control two types of contacts, both makes which close when the relay operates and breaks which open when the relay operates. A complete relay may be compared to a proposition which is sometimes true (operated) and sometimes false (released) and the contacts on this relay correspond to the use of this proposition in proving other propositions. A relay circuit thus is a collection of open and closed propositions.

Requirements for relay circuits are usually stated on a cause and effect basis; that is, when "such and such" events happen in a certain way, certain effects will be produced. If a clear logical statement of the relations between certain causes and the desired effects can be made, it is usually a simple matter to construct a circuit of relays controlled by contact networks which is analogous to the logical statement and consequently produces the desired results. Flaws in the logical reasoning will produce corresponding flaws in the circuit leading to inopera-

Figure 1 Circuit networks as statements of conditions for closing a path

tive conditions. Also restrictive conditions such as apparatus limitations may not always permit us to use the simplest straightforward solution.

The causes, constituting the input or control conditions for a relay circuit must result, directly or indirectly, in the closure (or opening) of an electrical contact suitable for operating a relay. Thus the control conditions may be: the manual operation of a push button; the closure of a contact by the mechanical motion of some instrument or machine; the insertion of a plug into a jack; or the closure of relay contacts in other associated circuits.

If the purpose of a relay circuit is merely to recognize the simultaneous occurrence of several control conditions and produce some output condition when this combination of conditions occurs, the correspondence between a statement of conditions and a relay contact network is very close. For example, if a lamp is to be lighted when two push button contacts, A and B, are both operated at the same time the statement of conditions for lighting the lamp is "A is operated *and* B is operated." The circuit path obviously is a series connection of make contacts. On the other hand, if the conditions are that the lamp shall light if "A is operated *or* B is operated," the circuit consists of a parallel connection of make contacts A and B. In the foregoing statements the words *and* and *or* have been italicized. These conjunctions in a careful statement of conditions for closing a circuit indicate whether a paralleled or series arrangement of the contacts is to be used, *and* indicating a series connection while *or* indicates a paralleled connection.

The same process may be applied to more elaborate statements. The path which is closed when "A *and* B are operated, *or* C is operated" is the series parallel arrangement of Figure 1(A) while the circuit which is closed when "A is operated *and* B *or* C is operated" is shown in Figure 1(B). A still more elaborate example is shown in Figure 1(C) where the path is closed when "A is closed *or:* B *or* C, *and;* D *or,* E *and* F are closed." The punctuation of the statement may become quite complicated but the above examples show that an accurate analysis of the requirements for closing a circuit will indicate directly a series parallel arrangement of the contact network. The point is not that a verbal statement of conditions for closing a circuit path is necessary or desirable but that the mental processes required in constructing and punctuating such a statement are the same as those required in designing the network. Note that the *or* indicating a parallel connection is not a mutually exclusive term. A parallel connection of two contacts A and B is a circuit which is closed when "A *or* B or *both* are closed."

A AND NOT-B, OR NOT-A AND B

Figure 2. Use of break contacts

It is important that statements of circuit conditions mean precisely what is intended. For example, consider a statement describing the control of circuit paths X and Y by contacts on relays A and B, "When A operates, path X is closed but when both A and B operate only path Y is closed." This does not specifically state the conditions for closing path X. What is meant is that X closes when "A is operated *and* B is not operated." When it is necessary to state that a relay is not operated or some condition is not present in order to describe a control condition the use of a break contact is implied. Another example is a statement such as "the path is closed when either A or B is operated" where the *or* is mutually exclusive and the circuit is open when both A and B are operated. A more exact statement of these conditions is, "A operated *and* B not operated, *or* A not operated *and* B operated." The circuit is shown in Figure 2 where transfer contact arrangements are used.

(A)

A AND,NOT-B OR C
(B)

Figure 3. Simplification by restatement

After a little study it becomes evident that the sketch of a network of contacts corresponds to a concise statement of conditions for opening or closing a circuit path The most concise statement of a set of conditions or, in other words, the contact network producing the desired results with the least number of contacts, is often reached only after several trials and restatements of the conditions. As a simple example, the circuit which is closed when "A is operated *and* B is not operated, *or,* A is operated and C is operated," as shown in Figure 3(A), may be restated as a circuit which is closed when "A is operated *and,* B is not operated, *or* C is operated." Since the element A is mentioned only once, a single A contact is sufficient as shown in Figure 3(B).

The practicing circuit designer seldom makes actual verbal or written statements of circuit conditions, but sketches the circuits themselves as the most direct way of expressing the requirements or conditions of a circuit. Often the original circuit contains many superfluous contacts, the important point at this stage being to insure that the various contact networks are closed for all required conditions and not closed for any conditions likely to produce undesirable reactions. Next comes the process of simplification, an elementary example of which was shown in Figures 3(A) and 3(B). All of this requires considerable attention to detail and logical analysis. The designer must keep in mind the positions of all relays of the circuit at any given time, and must visualize the reactions which take place when a contact network closes to operate a relay whose contacts in turn open or close to cause other relays to act, causing still further reactions. An experienced designer often conceives his original circuit network in their simplified forms. After a certain amount of practice, intuition for the construction and simplification of contact networks develops from the repeated application of logic to problems of cause and effect.

The algebra of logic, or Boolean algebra, has been applied to problems of contact network configurations.[1] This is a 2-valued algebra which deals with propositions in logic which are either true

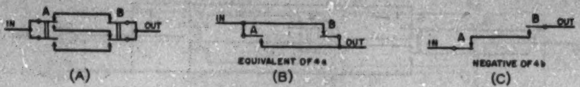

Figure 4. Negative reasoning

or false. Since a contact also is 2-valued, the theorems of this algebra concerning the combination of several propositions into a single proposition also apply to the combination of contacts into a single 2-terminal network. When a network which meets requirements has been devised from a study of the conditions of a problem, this algebra can often be used to great advantage in simplifying the network and eliminating superfluous elements.

A different type of reasoning often leads more directly to the desired form of a contact network. This is, thinking in terms of open circuits or considering the conditions which must open a circuit path, rather than those which close it, and designing a network to satisfy these open circuit conditions. This can be characterized as negative reasoning. For example, consider a network on the contacts of two relays, A and B, which must be closed when "A *and* B are released, *or*, A is operated *and* B is released, *or*, A *and* B are operated." The network corresponding to this statement is shown in Figure 4(A). However, an analysis of the conditions shows that the path is closed for three of the four possible combinations in which A and B may stand operated or released, and is open only when A is released and B is operated. This analysis gives us the equivalent circuit shown in Figure 4(B) which is open only on this condition and consists of a make contact on A in parallel with a break on B.

Now consider the condition "A released *and* B operated." The circuit closed for this condition, a break on A in series with a make on B is shown in Figure 4(C). This circuit, 4(C), is open when that of Figure 4(B) is closed and closed when 4(B) is open. The two circuits are said to be "negatives" of each other. Either one or the other is closed for any given set of conditions but they are never both closed at the same time. Comparing the circuits of Figure 4(B) and (C), we see that where one contains make contacts the other contains break contacts and a series connection in one becomes a parallel connection in the other. It turns out to be a general rule that the "negative" of any series parallel 2-terminal network of contacts can be constructed by substituting break contacts for make contacts and vice versa, and interchanging series and parallel connections. Two examples are shown in Figure 5. Obviously a circuit can be constructed directly from a statement of conditions for opening a path by changing meanings of *and* and *or* to parallel and series, respectively, and using break contacts on operated switches or relays and make contacts on unoperated switches or relays. The negative type of reasoning often leads more directly to simplified circuit arrangements. It may be used as a check on circuit arrangements obtained by direct reasoning and the ability to readily construct the negative of any given circuit is a convenient tool in developing relay control circuits.

Example 1

Now let us consider a simple problem in logic to illustrate how a contact network analogy may be constructed, choosing a problem which is obviously one of logic and not electrical circuits. In this it will be seen that in order to develop the circuit the logic must be completely reasoned through. When this logic has been incorporated in the circuit, the circuit then "knows" the correct answers and will deliver them without error. The problem is a simplified version of the well known "wolf, goat, and cabbage" puzzle:

A farmer has entrusted the care of a goat, a wolf, and a quantity of cabbages to a not-too-intelligent hired man. These items may be kept in either of two barns. If the goat is left alone with the cabbages it will eat the cabbages, while the goat himself is subject to being devoured by the wolf if the hired man is not present to intervene. The farmer desires a device to check on the hired man which is to consist of keys W, G, C, and M, representing the wolf, goat, cabbages, and hired man, respectively. By observing the contents of one of the barns and operating the corresponding keys, the farmer is to be warned by the lighting of a red lamp if the hired man is not properly fulfilling his duties.

For a logical analysis of the problem, first consider the situation in a particular barn under observation. If the hired man is not present and the goat is present with the wolf or the cabbages, trouble will occur in that barn. A more concise statement is "M absent *and* G present *and*, W *or* C present." Items absent from one barn must be present in the other so that a similar statement concerning items not observed describes conditions for trouble in the other barn. The statement is "M present *and* G absent *and*, W *or* C absent." Networks can be constructed from these statements, "present" indicating a make contact and "absent" a break. Since trouble will occur if one *or* the other of these statements is true the two net-

(A)

SERIES-PARALLEL EQUIVALENT
(B)

Figure 9. Bridge circuits

works must be placed in parallel. This is shown in Figure 6(A) where a bar over a designation indicates a break contact. The equivalent schematic is shown in Figure 6(B). With this device it is necessary only that a person be able to identify the items in one of the barns. No analysis or even knowledge of the habits of wolves or goats is required. The contact network having been developed to correspond to a logical framework will examine input conditions to produce answers according to this logic.

Now suppose that the farmer, after using the foregoing device for some time and losing a quantity of cabbages due to a burned-out warning lamp, requests that a green lamp also be provided to indicate as a check that conditions are satisfactory. Thus, the red lamp will light when the hired man is in trouble, and the green lamp when the situation is under control. For this circuit we may simply construct the negative of Figure 6(A) without further analysis of the problem. The resulting network is shown in Figure 7(A) which is the negative of Figure 6(A). An experienced designer will combine and rearrange the complete circuit for both lamps in the equivalent form shown in Figure 8. We leave to the reader the design of a suitable carrying case for the device.

Further Aspects of Contact Networks

The human mind seems to function most often in *and* and *or*, or series-parallel type reasoning, and all networks developed directly by processes described before are of the series-parallel type. By using bridge-type configurations, a contact network may describe a set of conditions much more concisely than it may be stated in words or even thought about. This can be shown by the example of the two jealous wives whose husbands may not take a canoe ride with the other wife except if accompanied by a chaperon. The conditions for a couple to take a canoe trip are concisely expressed by paths through the bridge network of Figure 9(A) where W_1 and W_2 represent the two wives, H_1 and H_2 their respective husbands and C designates the chaperon.

Table I. Representation of Numerical Digits

Digit	Code A	Code B
1	A_1	B_0-B_1
2	A_2	B_0-B_2
3	A_1-A_2	B_1-B_2
4	A_4	B_0-B_4
5	A_5	B_1-B_4
6	A_1-A_5	B_2-B_4
7	A_2-A_5	B_0-B_7
8	A_1-A_2-A_5	B_1-B_7
9	A_4-A_5	B_2-B_7
0	None	B_4-B_7

A bridge-type network is one which has one or more cross branches between parallel branches. Figure 9(A) is an example of the simplest bridge, and a series-parallel equivalent is shown in Figure 9(B) where it is necessary to duplicate a number of the contacts. The conditions for closing this bridge network consisting of five contacts cannot be described adequately by mentioning each contact only once. A circuit network developed to satisfy given requirements originates usually as a series parallel arrangement. There seems to be no general method for converting a given series-parallel network to a bridge network, or even determining that an equivalent bridge network is possible. Bridge networks with their resulting saving in contacts are developed usually by inspection and trial, followed by a careful check that the bridge is opened and closed under all the conditions of the original problem.

A given number of relays or switches, n, may stand open or closed in 2^n possible combinations. That is, a single relay may be either operated or released, two relays, A and B may stand in four combinations, namely, both released, A operated, B operated, or both operated. Three relays give eight combinations and each additional relay doubles the number of combinations. A circuit path can be developed for each of these combinations which is closed only when this combination occurs and open during all others. In fact, a network can be developed which is closed for any set of combinations and open for all others. In the problem of the farmer there are 16 ways in which the wolf, goat, cabbages, and man can be placed in and out of the barn and the circuit for the red lamp is closed for six of these combinations. A routine method for constructing

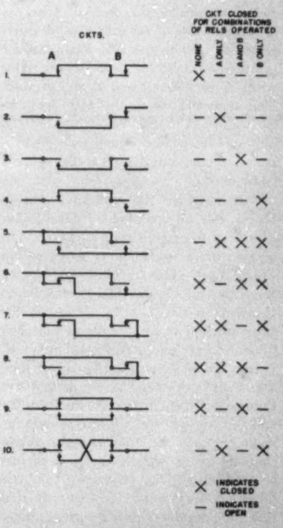

Figure 10. The ten different circuits on the contacts of two relays

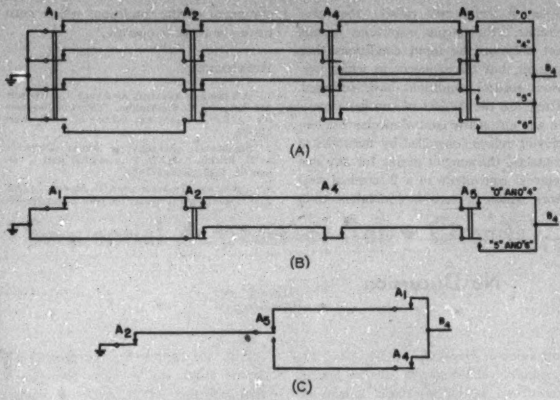

Figure 11. Development of network for one output lead

a network closed for any set of combinations of given relays is to first construct the path for each individual combination. Each of these consists of a series chain of one contact on each relay, the contact being a make or a break, depending on whether the relay is operated or released in that combination. The final network may be obtained by placing all of the individual chains in parallel and simplifying the resulting network.

A surprisingly large number of distinctly different paths may be constructed on the contacts of a few relays. Consider the case of two relays which may stand in for different combinations. The four combinations may be designated as either open or closed in 16 ways, and 16 corresponding circuits developed. Of these, one is an open circuit, one is a closed circuit, four require contacts on only one relay, and the remaining ten require contacts on both relays and are all different. These are shown in Figure 10. For three relays the number of distinctly different arrangements is 218, which indicate how rapidly the complexity of a relay circuit arrangement may increase as the number of relays increases.

EXAMPLE 2

An example from telephone switching practice will illustrate further the process of developing contact networks. In telephone switching systems numerical digits such as those of a directory number are recorded by operating a set of relays in distinctive combinations corresponding to the numerical digits. For various reasons a number of different "codes" are used and it is sometimes necessary to convert from one code to another.[3] Two such codes are shown in Table I.

The circuit example will be that of an arrangement to convert from code A to code B. The elements of code A consist of four relays designated A_1, A_2, A_4, and A_5 which are operated in combinations of one, two, or three at a time to represent the digits as shown. A contact network on these relays is required to ground five output leads, B_0, B_1, B_2, B_4, and B_7 two at a time as in code B. These codes are both additive codes in that the sum of the designation subscripts adds up to the digit value (with the exception of zero in the B code).

The procedure for developing the contact network is to first consider separately each output lead in the B code, examine the individual conditions which cause this lead to be grounded, and construct a contact network which is closed for only this set of conditions among all the conditions which may occur. When networks for all the output leads have been developed it may be possible to partially combine them to save contacts. To illustrate let us develop the network for output lead B_4. This must be grounded for four of the digits represented in the A code as shown in Table II.

Table II

Digit	A Code
4	A_4
5	A_5
6	A_1-A_5
0	None

In developing circuit paths, the effect of unoperated as well as operated relays must be considered. For example, the A code for digit four is not only A_4 operated but also A_1, A_2, and A_5 released. The corresponding circuit path consists of a series chain of breaks on A_1, A_2, and A_5 and a make on A_4. This path is shown together with those for the other three digits in Figure 11(A) where the branch paths are designated according to the digit they represent. This network meets the basic requirements for grounding lead B_4.

It obviously contains superfluous contacts and can be simplified by Boolean algebra or by inspection and logical analysis. An intermediate stage of the simplification is shown in Figure 11(B) and the final form in Figure 11(C). Note the curious fact that this particular network contains only one make contact. The circuit achieves the desired result mainly by opening the circuit path during undesired combinations.

The networks for the remaining B leads are developed in a similar manner and produce arrangements which are

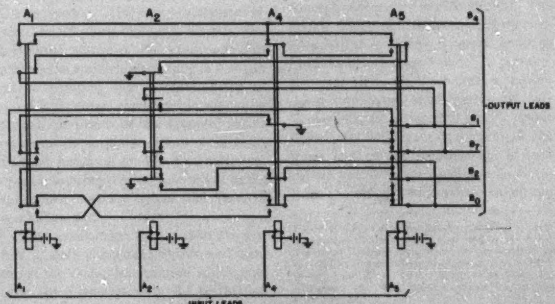

Figure 12. Complete code conversion circuit

somewhat more complex than that of the B_4 lead used for an example. The networks for all five of the B leads may be combined by inspection and analysis to produce the complete network shown in Figure 12.

Circuits such as this where there is a one-to-one correspondence between combinations of input control condition and output conditions are called "combinational circuits." In circuits of a higher order of complexity called "sequential circuits," the output conditions depend not only on the input conditions then present, but the sequence in which previous control conditions have occurred. These are the subject of another paper.[2] In any automatic control mechanism employing relays controlled by networks of contacts, the control means for any one relay is equivalent to a 2-terminal network which in turn is equivalent to a statement of the conditions which must cause the relay to operate.

No Discussion

Sequential Aspects of Relay Circuits

A. E. RITCHIE
NONMEMBER AIEE

IT IS well recognized that the electromagnetic relay is the basic circuit element employed in the control of present day automatic telephone switching systems. Although the relay is fundamentally a very simple device capable of assuming but two conditions, unoperated and operated with contacts correspondingly open or closed, it possesses certain properties which enable it to be woven into amazingly complex circuit arrangements. It is but a slight exaggeration to claim that relay circuits can be designed to perform any logical operation of which the mind of man can conceive, provided that there are a finite number of input and output conditions which can be translated into the relay "language."

The basis of relay circuit action is that a set of n of the 2-position devices can assume 2^n distinct combinational patterns. Thus a particular input condition can produce a particular relay pattern which by utilizing the contact configurations on the relays generates a corresponding output condition. A new input condition develops another output condition, and so on. This combinational aspect of relay circuits is the subject of other papers.[1,2]

Of equal importance with this concept is the realization that an input combination to a relay circuit can generate an internally-used condition which can be locked-in, so to speak, for future use. Such internal registrations can be employed to modify the reaction to subsequent input conditions or to originate a series of internally-controlled output conditions, which proceed, once started, independent of the input. These considerations all imply a sequential aspect to relay circuits which will be the subject of this paper.

An excellent example of the sequential capabilities of relay circuits is offered by the control circuits of a modern telephone switching system. Although in detail the control circuits are incredibly complex, the over-all input and output conditions are sufficiently well known to permit a ready understanding of the nature of sequential relay circuit action. A brief description of switching control will be followed by a discussion of some of the factors that enter into the design of sequential relay circuits.

The control action necessary to establishing a telephone connection can be broken down into two principal series of operations. One concludes when the subscriber hears dial tone; the second when a distant bell rings. The first is initiated when a subscriber lifts his receiver to place a call. This action produces a simple input condition to the switching system consisting of the closure of the conductor loop to the central office. Circuits within the central office recognize this loop closure and call into action associated circuits which interact with each other to find the one calling line out of perhaps 10,000, locate one out of perhaps 100 register circuits capable of receiving dialed instructions, and finally, test and set up a connecting path from line to register. This simple statement of what takes place indicates directly the sequential nature of the operation; implied is the sudden burgeoning of a single relay operation into a multiplicity of secondary control conditions in which the output conditions of one group of relays represent the input conditions of the next. In total, hundreds of individual relays cooperate to bring the dial tone signal to the subscriber, usually before the receiver reaches his ear.

The second input condition to the system is more complex in nature and comprises the dialed information which contains the directions as to the destination of the call. The very problem of accepting and registering this information requires for its solution an involved sequential-type relay circuit part of which is the subject of another paper.[3] However, assuming that the dialing of a 7-digit number represents a single input condition, consider the magnitude of the response required from the switching system. A particular 7-digit number is one condition out of a possible 10,000,000. Relay circuits must determine from this unique number the general location or central office of the called line and test and set up a connection to an idle path leading to that office. Complex signals representing the called line number are then transmitted over the established path and are registered at the distant office. This information must in turn be interpreted and used to control circuits which guide the connection toward the particular called subscriber. Finally, a bell starts to ring, and continues until the call is either answered or abandoned. At any point in this series of events, the relay circuits must be prepared to start out on alternate sequences of operations depending upon particular conditions encountered.

Basic Design Principles

This brief description is an oversimplification of the control features of telephone switching, but it will perhaps serve to illustrate the nature of the capabilities of relay circuits and to indicate the concept of sequence in such circuits. The actual design of circuits to perform such a variety of functions, however, is not as formidable as it may sound. In practice, the over-all control problem is broken down into many small parts and particular jobs are assigned to specific circuit units. By intelligent statement of the input and output requirements of each circuit unit a set of conditions is established, to satisfy which a relay circuit can

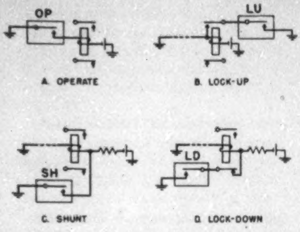

Figure 1. Basic control paths for a relay

be designed. The basic design technique for sequential-type circuits is outlined in this section and is followed in the next by an application to a practical design problem.

Underlying the technique of relay circuit design is an understanding of the basic relay control paths. There are four of these paths, illustrated on Figure 1, which may be defined as follows:

Operate. A battery-ground path in series with the relay winding and containing a network *OP* developed on the contacts of other relays. When the contact configuration closes the path, the relay operates; when it opens the path, the relay releases.

Lock-Up. A path to the relay winding through a make contact on the relay itself. The lock-up path is ineffective until the relay is energized through the operate path. Thereafter contact network *LU* on other relays can hold the relay operated until *LU* opens the lock-up path.

Shunt. A path in parallel with the relay to a series current limiting resistor. Its functioning is the inverse of the operate path. When the operate path has been closed, closure of contact network *SH* on other relays releases the relay; opening *SH* permits the relay to operate.

Lock-Down. A path shunting the relay winding through a break contact on the relay itself. When the relay is released, a closed-path through network *LD* on other relays prevents it from operating; opening *LD* permits it to operate. This path is ineffective when the relay is operated and is the inverse of the lock-up path.

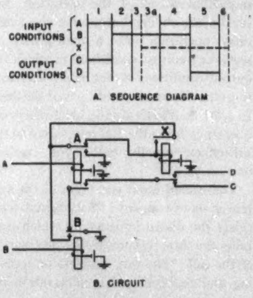
Of these four paths, the operate and lock-up are by far the most frequently used. The two shunting paths, however, can be very useful in certain circuit situations which in general can be recognized easily. An example is when a relay is required to operate to record the termination of a pulse.

The nature of input conditions to a relay circuit is also obvious from Figure 1. In general they consist of the simple presence or absence of ground (or battery) on leads to the circuit. This statement ignores special relays which respond to polarity or to alternating current, and which are not considered in this paper. The complexity of a set of input conditions depends upon their combinational or sequential aspects rather than upon their basic nature. The output conditions which relays can establish are similar to the input conditions in that they consist of the closing or opening of paths. These paths can light lamps, ring bells, actuate other relays, and so forth, but again are fundamentally simple in nature.

It is convenient in designing relay circuits to associate a relay with each input path. These primary relays will then accurately follow the various input conditions and offer in effect sets of contacts for manipulation. If at a later stage in the design a primary relay is found to require only a single make or break contact, it can perhaps be dispensed with.

The input conditions to a relay circuit may consist of one or more unique signal combinations with each of which a particular and unvarying output condition is associated. Circuits of this type may be characterized as combinational. In this case contact networks on the primary relays alone can usually be designed to complete the circuit. The more usual situation, however, involves a sequence of input conditions in which the reaction at each change of input depends upon preceding events. A particular input combination may be repeated more than once with a different output condition associated with each appearance. An input condition may initiate a series of output conditions or a group of circuits may interact to provide each other with consecutive instructions which determine from moment to moment the subsequent action. Circuits of this type are known as sequential circuits. They invariably require the use of secondary relays whose function is to record preceding events, to differentiate between repetitions of the same input condition, and to control sequential output conditions. Control of the secondary relays is through contacts on both the primary and secondary relays.

Figure 2. An example of sequential design



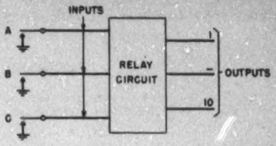


Figure 3. Block diagram of design problem

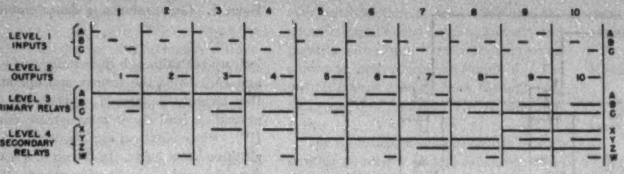
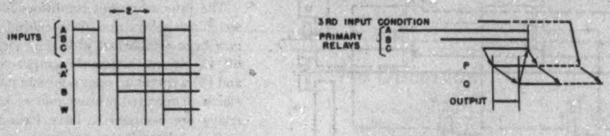
An illustration of a repetitive input condition is shown on Figure 2(A). The two horizontal lines *A* and *B* represent the sequential order of two input conditions which may be considered ground on leads *A* and *B*. The *A* condition first appears and then is joined by condition *B*. Condition *A* terminates and reappears during condition *B*, finally persisting for an interval beyond the removal of *B*. This representation constitutes a cycle and, if *A* and *B* are understood to be primary relays which follow the input signals, each successive relay combination is known as an interval. It can be seen that intervals 1 and 5 are identical as are 2 and 4. The circuit is required to develop distinctive output conditions for both intervals 1 and 5. Clearly an additional relay is necessary to differentiate between intervals 1 and 5. The secondary relay should, logically, be in an operated condition during one of the conflicting intervals and in an unoperated state during the other.

The general design procedure consists, first, of examining the sequence diagram to determine a plan of operation for the secondary relays or, basically, the intervals during which the secondary relays must be operated. Thereafter the control paths and the output paths can be designed. In this case, a single secondary relay (X) must operate after interval 1 and prior to interval 5. The primary combination to operate (X) must be chosen so that it does not appear before or during interval 1, and, in the general case, must not recur at any other time during which (X) must be released.

After the operate interval for (X) has been chosen, the release interval must be determined. Obviously, this must be later in the cycle than the intervals that (X) operated is required to distinguish and also it must not be duplicated within the operated period of (X). Once this interval has been established, the holding circuit for (X) can be developed in either



A. OVERALL SEQUENCE DIAGRAM



B. END-OF-PULSE DETECTION

C. OUTPUT TIMING AND RELEASE

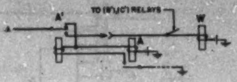


Figure 4 (left). Sequence diagram of design problem

Figure 5 (above). Circuit for detecting the end of a pulse

of two ways. One is to examine the release interval, determine a path through the primary relay contacts that is *open* only at that time, and connect the path to a lock-up contact on relay (X). The other method is to examine the intervals during which (X) remains operated, determine overlapping contact paths that remain *closed* until the release interval, and connect such paths in parallel to a lock-up contact on (X). Since the lock-up contact is closed only when (X) is operated, duplicate holding paths that are closed to this contact during intervals in which (X) is not operated can have no effect on circuit operation and need not be considered.

In the sequence diagram of Figure 2(A), interval 3 offers the unique primary combination of (B) alone operated for operating relay (X). Since (X) must remain operated through interval 5, a suitable holding combination persisting during intervals 3, 4, and 5 consists of (A) or (B) operated. The complete circuit for the three relays including the output paths is shown in Figure 2(B).

In the general case of more complex circuits, a great many secondary relays may be required. Control paths for these involve not only contacts on the primary relays, but on the secondary relays themselves. It is frequently necessary to operate a particular secondary relay two or more times during a cycle. This requires placing several operate paths in parallel. If lock-up paths are developed from overlapping holding combinations, several of these may be placed in parallel. On the other hand, if holding paths are derived from consideration of the release intervals and are chosen to open only at the correct instant, they may be placed in series. In any case, considerable care is necessary to determine the optimum position of a secondary relay in a cycle and to design good control paths.

A very important factor in design, mentioned earlier, is that a group of n relays is capable of assuming 2^n different combinational patterns. Since, in general, each interval of a complete cycle including both primary and secondary relays should represent a distinct combination, this is a clue to the maximum number of relays required. In Figure 2, the original statement of the problem called for five distinguishable intervals necessitating at least three relays. Introduction of the third relay into the cycle differentiated between intervals 4–5 and 1–2 and also created two new intervals, 3a and 6. These latter occur because of the finite operating time of a relay. It is generally true that, with the larger circuits, as the ratio of used combinations to total combinations increases, circuit complexity goes up rapidly. Therefore, it may be desirable to add more secondary relays to a circuit than logic strictly calls for.

The design of relay circuits in which sequential output conditions are generated internally by the circuit follows the same general technique as that described before. Building on a sequence diagram of input conditions, the output conditions are plotted and then the secondary relays are added to satisfy the requirements. Considerable care must be exercised in choosing the secondary relay pattern since the sequence may have a profound effect on the complexity of the over-all circuit. Frequently the design of internal control and output paths indicates desirable modifications of the cycle.

Design Problem

The discussion up to this point has been very general in nature, and perhaps requires an example of actual circuit design to illustrate the technique. The problem that follows is not taken directly from telephone switching systems, yet it is closely related to a type of circuit situation that recurs in switching design.

A 3-button key set, each button actuating a single make contact, is connected over three wires to the relay circuit to be designed. This is indicated on Figure 3. Input conditions consist of three successive key operations, with the restriction that the same key may not be operated twice in a row. This permits 12 permutations of key sequences of which ten are required to produce individual output conditions. The output conditions are to consist of a short ground closure, following the third key operation, to the one out of ten output leads corresponding to the input sequence. Following the output signal, the circuit must return to normal.

On levels 1 and 2 at the top of the sequence diagram of Figure 4(A) are plotted the ten individual input sequences or cycles, each associated with a particular numbered output. Since the only difference between the various input sequences lies in the order of key closures, basically the relay circuit must be a sequence-detecting device. Furthermore, it must recognize three key operations, not necessarily on three different keys, before producing an output.

Since the three input conditions of an individual sequence do not overlap, relays must record by locking-up that a particular input has occurred. In this particular case, it is advantageous to lock-up the primary relays for this purpose in order to simplify the control of secondary relays. On level 3 of Figure 4(A), the condition of primary relays as a result of this assumption is shown. It will be

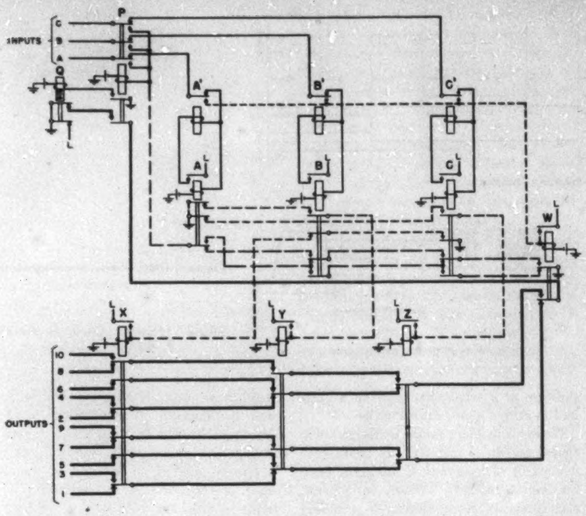

Figure 6. Circuit solution to design problem

noted that, at the end of each odd input cycle, all primary relays are operated; at the end of each even cycle, two of the three primary relays are operated. Clearly secondary relays are necessary to distinguish between the identical primary combinations.

If the primary cycles are examined in order, it is seen first that the final combination of cycle 3 must be differentiated from that of cycle 1. Since cycle 3 differs from cycle 1 only in that relay (C) operates before relay (B), a secondary relay (X) can be specified that will operate in cycle 3 through a make contact on (C) and a break contact on (B). This path, which detects sequence, is not closed in cycle 1. However, it is closed in cycles 4, 9, and 10 and relay (X) should be entered on the sequence diagram at all four places as shown on level 4 of Figure 4(A).

Similar analysis discloses that a secondary relay (Y) operating on the combination of (B) operated and (A) released will differentiate between cycles 1 and 5. Relay (Y) also operates during cycles 6, 7, 8, 9, 10. Interval 7 is now indistinguishable from interval 5. Therefore, relay (Z), which detects the sequence of (C) operating before (A) is added to cycles 7, 8, 9, 10. At this stage of the development a unique combination of relays (A), (B), (C), (X), (Y), (Z) exists at the end of each cycle and appropriate output paths could be constructed on the contacts of the relays.

However, further study of the sequential diagram will show that there is no present means of detecting the arrival of the third, duplicating, input on the even cycles. This is necessary primarily to indicate when the output path should be closed. A secondary relay (W), operating as shown on level 4 of Figure 4(A), could well perform this function. There is no convenient way, however, to provide the correct operating paths for (W) using only the relays already shown on the sequence diagram. Additional relays are required which can react to the termination of the first appearance of each input closure and prepare a path through which a second appearance can operate (W). The nature of the problem is such that it makes no difference which repeated input operates (W).

The sequence diagram for a typical individual cycle is shown on Figure 4(B). Input *A* causes primary relay (A) to operate and lock. Directly below (A) is shown an auxiliary relay (A′) which operates and locks when input *A* ends and which serves to provide a unique combination to operate (W) when input *A* reappears. Since the operating condition for auxiliary relay (A′) consists of the removal of a ground closure, a lock-down path is necessary for its control. A frequently used circuit arrangement that meets the sequential requirements perfectly is shown in Figure 5. Initial grounding of lead *A* operates relay (A), yet prevents (A′) from operating. When ground is removed from lead *A*, the series lock-up path through the windings of (A) and (A′) holds the former and operates the latter. A second appearance of ground on lead *A* can now operate relay (W). Since identical conditions apply to all three input leads, the circuit of Figure 5 can be used in conjunction with each of them.

The internal circuit conditions for the secondary relays and their control have now been established with the exception of: (1) means to time the output signal; and (2) a circuit to open a ground path to which all operated primary and secondary relays are assumed to have locked. A sequence diagram for two relays to perform these functions is shown in Figure 4(C).

Relay (P) operates when the third input condition in any cycle appears and must, first, close ground to the signal output paths on the secondary relays, and second, close a path to slow-acting relay (Q) which, when it operates after a time delay, will open the output path. If locking ground for the circuit as a whole is taken from a back contact on relay (Q), the circuit will release at the termination of the output condition.

A careful analysis of the conditions represented by Figure 4(C) will indicate the possibility of the third input condition persisting beyond the release of relay (Q). If this were to occur, a primary relay might reoperate to initiate falsely a new cycle. In order to prevent this, it can be decided now to take the input leads through break contacts on (P) and to provide locking contacts on (P) to permit the relay to hold to any activated input lead.

All information required for setting up the final contact paths of the completed circuit is now available. The circuit itself is sketched in Figure 6. The control paths for the primary relays (A), (B), (C) and their auxiliaries (A′), (B′), (C′), identical to that shown in Figure 5, are drawn in light lines. Control paths for secondary relays (W), (X), (Y), (Z), derived from sequence diagram levels 3 and 4 of Figure 4(A) and from Figure 4(B), are shown in short dashed lines on Figure 6. The operating path for relay (P) requires somewhat more consideration. Relay (P) must operate under a variety of conditions which include (A), (B), (C) all operated and [(A), (B)] or [(A), (C)] or [(B), (C)] operated in conjunction with (W). A path designed on this basis would be very cumbersome. However, all these conditions are embodied in the statement that (P) must operate when any three of relays (A), (B), (C), (W) are operated. This permits use of a symmetric three-out-of-four contact network,[2] shown in long dashed lines, to control (P). Also relay (P), as stated before, must lock to all input leads and must open the input leads to the primary relays.

The original conception of the output path network visualized contacts on relays (S), (Y), (Z), (A), (B), (C). However, introduction of relay (W) into the circuit simplifies the output network and permits use of the "tree" configuration[2] shown in heavy lines in Figure 6. The output circuit extends back through contacts on (P) and (Q) for timing purposes.

The final design detail consists of connecting all relay locking leads *L* back to a break contact ground on relay (Q). The circuit is now complete and may be checked against the initial statement of requirements.

Relay "Trees" and Symmetric Circuits

S. H. WASHBURN
NONMEMBER AIEE

BASICALLY, a telephone switching system performs a large majority of its functions as a result of the operation of groups of interconnected relays, or similar electromechanical devices. These relays control one another by means of contact networks, the configurations of which depend upon the requirements to be fulfilled by the relay circuits involved. Due to the complexity of modern switching methods there is an almost limitless variety of these circuits. However, there are certain types of circuit arrangements which are employed over and over again and have become, with usage, familiar to all engaged in the design of switching systems. This paper discusses two of these types: the relay "tree," and the symmetric circuit.

Relay "trees" and symmetric circuits are forms of combinational circuits. The combinational circuit, as opposed to the sequential type, recognizes and reacts to certain combinations of active input conditions, and establishes a particular output condition in response to each input combination. The operation of the sequential circuit, on the other hand, is further affected by the order in which input conditions are applied. For the purposes of this paper each input control lead to a circuit may carry an active input condition; the term "combination of conditions" refers to the state of a group of input leads, each lead in either an active or a passive state.

The number of relays in a combinational circuit and the number of combinations of active input conditions it can recognize are directly related. A single relay, a 2-valued device either operated or released, can respond to only a single active input condition; that is, it can be operated by that condition and released by the absence of the active condition. Two relays can respond to four combinations of conditions: one combination operating one relay; one operating the second relay; the third operating both; and the fourth operating neither. Such reasoning shows that the number of combinations of input conditions which an n-relay network can recognize is 2^n. For each combination of input conditions causing circuit action, the relay circuit can produce a unique output condition (a grounded lead, for example). Thus, the number of independent and mutually exclusive output conditions possible for an n-relay circuit is 2^n. This same relationship can be given by the expression

$$\sum_{r=0}^{n} C_r^n$$

the sum of combinations of n relays of which r are operated. This summation is the number of combinations in which n relays may be operated and is equal to the number of possible independent output conditions, 2^n.

Relay "Tree" Networks

The relay tree, so-called because of its configuration, is a special case of a multiterminal network of relay contacts comprising a single input terminal which may be connected to one of a number of output terminals. The path from each output terminal to the input end of the network passes through contacts on all of the relays upon which the network is constructed and all paths are disjunctive; that is, only one is closed at a single time and no two paths are connected together. The particular path closed through depends upon the combination of operated relays.

The Fully-Developed Tree

In the fully-developed tree there is an output terminal corresponding to each of the 2^n possible output conditions. As an illustration, consider the fully-developed 4-relay tree of Figure 1. This network has $2^4 = 16$ output terminals. If the acting times of the relays are assumed to be negligible, it then follows that one and only one path from the input to an output terminal is always closed, the particular path depending upon the input combination placed on the four input control leads. The use of break-before-make transfers in the tree insures that no output terminals are connected together at any time.

Due to the orderly pattern on which the fully-developed network is constructed, certain relations hold between the number of circuit relays, the number of contacts in the circuit, the maximum number of contacts, on a relay, and so on. Designating the circuit relays in order of increasing number of contacts, relay R_1 is equipped with one transfer-contact; relay R_2, two transfers; R_3, four transfers; relay R_n, the maximum number of trans-

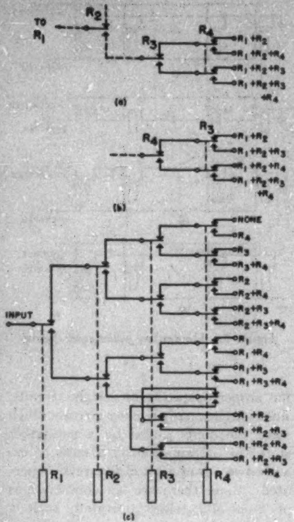

Figure 2 (right). Redistribution of the spring load on the relays of the tree

fers, 2^{n-1}. The total number of transfers in the circuit is the summation: $2^{n-1}+2^{n-2}+\ldots.2^1+2^0=2^n-1$.

An obvious disadvantage of the tree network in its general form is the unequal distribution of spring load on the circuit relays. A somewhat more uniform distribution may be obtained by manipulation of that portion of the network carried by all relays except the first, that equipped with the single transfer combination. Unfortunately, any contact rearrangement which adds to the spring load on the first relay greatly increases the total number of contacts in the circuit. This is not, of course, true of the trivial rearrangement in which all contacts on relay R_2 are transferred to relay R_1 and those on R_1 are placed on R_2.

The fully-developed n-relay tree may be considered as two $(n-1)$-relay trees, or as four $(n-2)$-relay trees, and so on, suitably connected. Inspection of the tree of Figure 1 indicates that it can be divided into two 3-relay trees, or four 2-relay trees. Contact rearrangement may best be carried out by successive manipulations of these minor trees, such manipulation having no effect upon the operation of the tree as a whole. There appear to be no specific rules for obtaining a rearrangement which provides a certain desired spring load distribution. The method of rearrangement described in the following must be applied on a successive-trial basis until a permissible distribution is attained.

The rearrangement of a minor tree consists merely of redesignation. For example, consider the lowermost of the four 2-relay minor trees on relays R_3 and R_4 of Figure 1, as redrawn in Figure 2(A). The designations of the two relays are interchanged, as far as this particular minor tree is concerned and, the output terminals are redesignated, as in Figure 2(B). Since the minor tree has a separate output terminal for each combination of the operated relays upon which it is built, such a redistribution of contacts results in a second minor tree which is the exact equivalent of the first. The rearranged minor tree of Figure 2(B), then, can be inserted in the complete tree in the place of the minor tree of Figure 2(A). This manipulation has, in effect, removed one transfer-contact from relay R_4 and has added it to the load on relay R_3, as shown in Figure 2(C).

Further load equalization is accomplished by rearranging the lower of the two 3-relay minor trees of Figure 2(C), interchanging the spring loads of relays R_2 and R_4 and thus moving two transfers from R_4 to R_2. The final exchange leaves the circuit with the following spring loads: R_1, one transfer; R_2, four transfers; R_3, five transfers; R_4, five transfers. In this manner the spring load may be shifted as desired, the total number of transfer-contacts always remaining 2^n-1.

THE PARTIALLY-DEVELOPED TREE

In many cases a tree network is not fully-developed; that is, not all possible combinations of operated relays have corresponding outputs. This type is more common in relay switching applications than the fully-developed form. As an illustration of the utility of a partially-developed tree, assume that a circuit is to be designed to fulfill the following requirements.

There are four leads a, b, c, and d which are grounded two at a time to indicate a digit from 1 through 5 in the following code: a and b = 1, a and c = 2, a and d = 3, b and d = 4, c and d = 5. The circuit to be designed is a translator which will ground one of five leads, each corresponding to an input digit. An additional requisite is that when any combination of grounded input leads other than those denoting the above codes occurs, no output lead is to be grounded. Output leads are to be disjunctive.

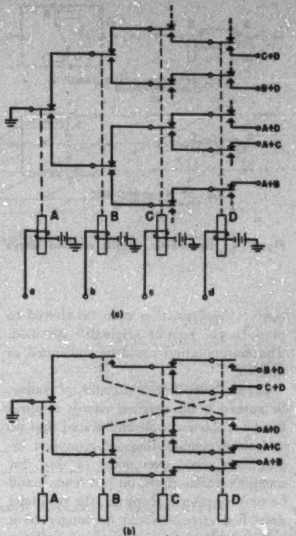

Figure 3. A partially-developed 4-relay tree used as a translation circuit

As a first step in synthesizing the desired circuit, relays (A), (B), (C), and (D) are provided, each relay to be operated when its corresponding input lead is grounded. The number of possible relay combinations for four relays, as has been indicated, is sixteen and, of these, five are to be used in the present circuit: an output lead, 1, is to be grounded when relays (A) and (B) are operated, output lead, 2, is to be grounded when relays (A) and (C) are operated, and so on. No lead is to be grounded for the remaining 11 combinations. The tree network of Figure 1 placed on the four relays will satisfy these requirements, and those elements of the tree which do not contribute to the grounding of the five required output leads can be eliminated. The resultant partially-developed tree is shown in Figure 3(A). Inspection shows that the circuit meets the original specifications.

The network of Figure 3(A) can be manipulated in a manner similar to that described previously. However, mere interchange of designations of the minor-tree relay contacts is not sufficient when the tree is not fully-developed. This is indicated in Figure 3(B) in which the upper minor-tree on relays (B), (C), and (D) of Figure 3(A) is rearranged. The

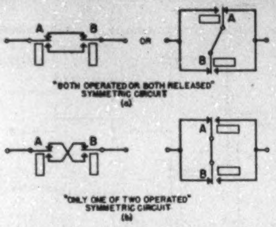

Figure 4. Symmetric circuits on two relays

contact configuration must be altered to produce the output originally specified. The manipulation could be continued as desired.

Greater simplification could, of course, be gained if the original circuit requirement for this example had stated that no undesired combinations of grounded input leads could ever occur or that, for certain combinations, output leads could be tied together. However, the resultant simplified circuit would no longer be a tree since, by definition, network paths in a tree must pass through contacts on all relays and must be disjunctive.

Symmetric Circuits[1]

A symmetric relay-contact network is one in which the conditions for closing a particular input-to-output path are given, not in terms of the designations of relays operated and unoperated, but in terms of the number of relays operated and unoperated. For example, a network which is closed when any three, and only three, out of five relays are operated is a symmetric circuit. A second example might be a network in which one path is closed when less than two circuit relays are operated and a second is closed for more than four relays operated. Chains and parallel groups of make-or-break contacts are elementary forms of symmetric networks since they can indicate conditions of all relays operated or released, or one-or-more relays operated or released.

There are two general symmetric networks which may be constructed on two relays, as shown in Figure 4, and each of these may be connected in two ways. These networks are closed for "both operated or both released" and "only one of two operated," respectively. This second network is of interest in that in the statement setting forth conditions for circuit closure, "relay (A) *or* relay (B) operated," the "or" indicates mutual exclusion: no path is closed when both (A) and (B) are operated. This "or," then differs from the "or" which appears in statements illustrating the operation of a network of parallel contacts.[3]

Numerous simple symmetric circuits based on chains of make-, break-, and transfer-contacts combined in various configurations can be developed. Some of these are shown in Figure 5 together with the associated conditions for circuit closure. For several of these networks two output terminals are shown, one for each closure condition of the network. The two terminals in these cases may be connected together if only a single path is desired for both conditions.

A network for any symmetric circuit may be constructed of series and parallel elements. Such a network, however, is generally complicated and uneconomical of contacts. A general type of lattice structure which gives the most satisfactory circuit is shown in Figure 6. This figure indicates the circuit in conventional form and also in a symbolic notation in which each contact is represented by a line segment. In this notation make-contacts are characterized by sloping lines and break-contacts, by horizontal lines. These elements are so arranged that contacts on a particular relay appear as line segments placed one above another, each vertical group of segments having the same designation as that of the corresponding relay. Inspection of the circuit in conventional notation indicates that the network paths are disjunctive and that the particular output terminal which is connected to the input terminal depends only upon the number of relays operated. The output terminals are designated to correspond to the number of operated relays or to the number of input control leads grounded.

The operation of the circuit can be seen more readily from the symbolic diagram. If ground is applied to the input terminal and no relays are operated, ground will be connected through a chain of break-contacts on the zero level of the diagram to the output terminal "O". If any one relay is operated, ground will pass along the zero level until it encounters the make-contact on the operated relay where it will be switched up to the next or first level. The ground then remains on the first level and appears on terminal 1. If more than one relay is operated, the ground is passed from one level to the next higher level at each operated relay. The highest level reached corresponds to the number of relays operated.

One important function which the symmetric circuit performs in telephone switching applications is that of checking for proper operation of certain circuits. For example, many register circuits which store the digits dialed by a subscriber store this information on a basis of exactly two out of a set of five relays operated. Since there are ten combinations of 2-out-of-5 relays operated, such a register can store any one of ten digits. However, under trouble conditions, more or less than two relays may become operated, mutilating the stored digit. So that this mutilation can not cause trouble in other circuits, it is desirable to include in the register arrangement a check circuit which will give an indication, or allow the stored digit to be passed on, only if the normal number of register relays are operated. A 2-out-of-5 symmetric circuit is an ideal arrangement for this application.

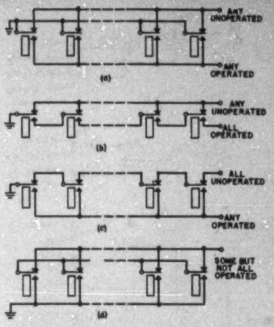

Figure 5. Elementary symmetric circuits

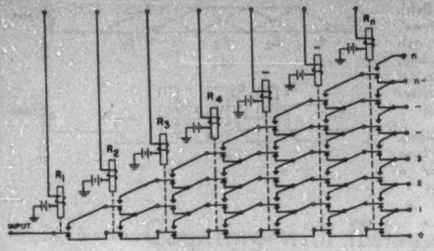
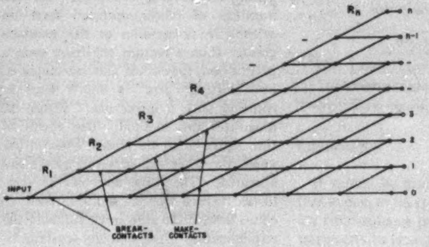
To satisfy a given condition with the general symmetric network, it is necessary only to connect to the input and to the desired output terminal. Superfluous contacts may be eliminated. The desired circuit for 2-out-of-5 relays operated is indicated in Figure 7, both as a lattice diagram and in more conventional form. Many of the junction points on the lattice diagram can represent transfers facing in either direction; an arrangement with fewer springs results if the circuit is drawn from both ends with transfers facing away from the end terminals. In the circuit of Figure 7 the (D) and (E) relays are inverted top-to-bottom to obtain a simpler schematic diagram.

SYMMETRIC CIRCUITS CLOSED FOR ONE CONDITION

As illustrated by the preceding example, if a symmetric circuit is closed for but one number of relays operated and the superfluous elements of the general symmetric



SCHEMATIC DIAGRAM
(a)



SYMBOLIC LATTICE DIAGRAM
(b)

Figure 6. General symmetric contact-network

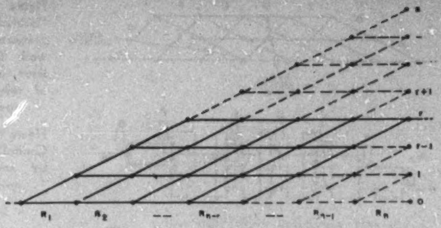


Figure 8. General single-condition symmetric network

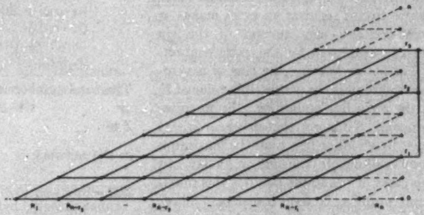

Figure 9. General multicondition symmetric network

are eliminated, the symmetric lattice becomes a parallelogram. A sloping side of this parallelogram consists of r elements, where r is the number of operated relays necessary for circuit closure, and the base is composed of $(n-r)$ elements, where n is the total number of relays in the circuit. The quantity $(n-r)$ has the significance of being the number of relays which must be *unoperated* to cause circuit closure. This generalized single-condition symmetric lattice is shown in Figure 8.

Considering the lattice, quantitatively, the total number of contacts, N, in the network is by inspection

$$N=(n-r)(1+r)+r(n-r+1)=2r(n-r)+n \tag{1}$$

The total number of make-contacts, M, represented by the sloping line segments, is

$$M=r(n-r+1)=r(n-r)+r \tag{2}$$

The total number of break-contacts, B, represented by horizontal line segments, is

$$B=(n-r)\ (1+r) \tag{3}$$

Considering now that make- and break-contacts may be combined to form transfer-contacts, either all makes or all breaks may be made parts of transfers depending upon which type of contact is lesser in number. The number of contacts which remain after the transfers are formed is given by

$$R=M-B=2r-n \tag{4}$$

The sign of R is positive if the remaining contacts are makes and negative if they are breaks.

The total number of transfers, T, is

$$T=(N-|R|)/2 \tag{5}$$

where $|R|$ is the absolute value of R.

Close inspection of the general symmetric lattice of Figure 8 indicates that the number of contacts on the most-heavily loaded relay depends not only upon the quantities n and r, but also upon whether $(n-r)$ is greater or less than, or equal to, r.

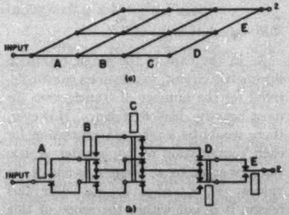

Figure 7. The 2-out-of-5 symmetric network

When $(n-r)>r$, or $n>2r$, the maximum number of contacts, N_1, on a relay is

$$N_1=2r+1 \tag{6a}$$

The number of transfers, T_1, obtained by combining these contacts, is

$$T_1=r \tag{6b}$$

and there is an extra contact, a break.

When

$(n-r)=r$, or $n=2r$,

$$N_1=2(n-r)=2r \tag{7a}$$

$$T_1=r \tag{7b}$$

and there are no extra contacts.

When

$(n-r)<r$, or $n<2r$,

$$N_1=2(n-r)+1 \tag{8a}$$

$$T_1=(n-r) \tag{8b}$$

and there is an extra make-contact.

These expressions make possible a determination of the symmetric networks of the greatest dimensions possible employing given relays. For example, assume that relays with a maximum of six transfers are available. If, however, the most-

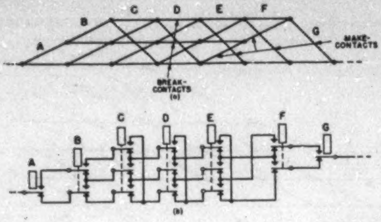

Figure 10 (left). "Shifted - down" symmetric network for zero, three, or six out of seven relays operated

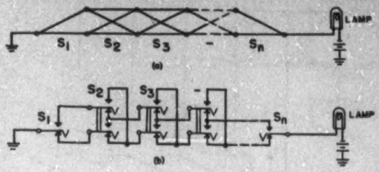
Figure 11 (right). Control of a lamp by any of n switches



heavily loaded relay in a particular symmetric circuit requires an extra make- or break-contact, one transfer of the six must be employed for the extra contact.

The factor limiting the size of a symmetric circuit is the permissible value of T_1 in the preceding equations. From equations 6 and 8 it is seen that either r or $(n-r)$ must be equal or less than the maximum number of usable transfers on a relay. In the cases of equations 6 and 8 this maximum number is five transfers. Thus, either the number of operated relays r, or the number of unoperated relays $(n-r)$, necessary for circuit closure must be equal or less than five. Equations 7 indicate a special case where $r=(n-r)$, and r may be equal to six. With the relays available, then, symmetric circuits may be constructed for the following conditions:

n	r
12 or less	12 or less
13	8 or more, 5 or less
14	9 or more, 5 or less
n	(n—5) or more, 5 or less

SYMMETRIC CIRCUITS CLOSED FOR MORE THAN ONE CONDITION

Thus far, only symmetric circuits which are to be closed for a single value of r, have been discussed. Circuits closed for several values of r may be designed by connecting together outputs of the general symmetric lattice of Figure 6 corresponding to the desired values of r and eliminating unnecessary elements. In Figure 9 is shown a lattice which is closed for r_1, r_2, and r_3 relays operated.

Consideration of Figure 9 indicates that the expressions for the total number of contacts, the number of make-contacts, the number of break-contacts, and so on, may be written for a general symmetric network to be closed when any r_1, r_2, $r_3, \ldots,$ or r_m out of n relays are operated.

The total number of contacts is

$$\overset{m}{\Sigma} N=[2r_1(n-r_1)+n]+[2(r_2-r_1)(n-r_2)+(r_2-r_1)]+[2(r_3-r_2)(n-r_3)+(r_3-r_2)]+\ldots.+[2(r_m-r_{m-1})(n-r_m)+(r_m-r_{m-1})] \tag{9}$$

The total number of make-contacts

$$\overset{m}{\Sigma} M$$

in the network is

$$\overset{m}{\Sigma} M=[r_1(n-r_2)+r_1]+[(r_2-r_1)(n-r_2+1)]+[(r_3-r_2)(n-r_3+1)]+\ldots+[(r_m-r_{m-1})(n-r_m+1)] \tag{10}$$

The total number of break-contacts is

$$\overset{m}{\Sigma} B=[(n-r_1)(1+r_1)]+[(n-r_2)(r_2-r_1)]+[(n-r_3)(r_3-r_2)]+\ldots+[(n-r_m)(r_m-r_{m-1})] \tag{11}$$

As before, make- and break-contacts are combined into transfers, and the number of contacts which are left over is

$$\overset{m}{\Sigma} r=\overset{m}{\Sigma} M-\overset{m}{\Sigma} B=(2r_1-n)+(r_2-r_1)+(r_3-r_2)+\ldots+(r_m-r_{m-1})=r_1+r_m-n \tag{12}$$

If the sign of the summation is positive, the remaining contacts are makes, or are breaks if the sign is negative.

The total number of transfers is

$$\overset{m}{\Sigma} T=(\overset{m}{\Sigma} N-|\overset{m}{\Sigma} R|)/2 \tag{13}$$

where

$$|\overset{m}{\Sigma} R|=\text{absolute value of } \overset{m}{\Sigma} R$$

As in the case of the single-condition symmetric circuit, expressions can be derived for the number of transfers on the most-heavily loaded relay. However, there would be a separate expression for each combination of $2_p\mathrm{I}$, greater or less than, or equal to, n, where r_p is one of the values: r_1, r_2, r_3, …., r_m. For this reason it is not within the scope of this paper to derive these expressions for even a small number of closure conditions.

"SHIFTING DOWN" SYMMETRIC CIRCUITS

Where a contact network is to be closed for several conditions and the numbers of relays operated form an arithmetic progression or the numbers greater than a certain one form such a progression, the circuit may be simplified by "shifting down" a higher level to coincide with a lower one. Figure 10 illustrates this method. The circuit of this figure is to be closed when either none, three, or six of seven relays are operated. The third level of the symmetric lattice can be shifted down to coincide with the zero level, fulfilling the requirements. Note that any level can be "shifted down" to any other level to meet the particular circuit specifications.

Although the utility of the "shifted-down" symmetric circuit is not great, one familiar example makes use of this method. In this example, a lamp is controlled by a number, n, of 2-position switches, S. Any switch can light or extinguish the lamp regardless of the positions of the other switches. These requirements may be fulfilled by a circuit in which the path supplying current to the lamp is closed when 0, 2, 4, …. switches are in their operated positions and open when 1, 3, 5, …. switches are operated. This circuit can be the "shifted-down" symmetric lattice, as in Figure 11, in which the third level is made to coincide with the first. This is, of course, the arrangement used in practice when several wall switches are to control a single lamp.

Counting with Relays

G. R. FROST
NONMEMBER AIEE

IN THESE days of automatic control of everything from scoring on pinball machines to supervision of big city subway systems,[1] relay circuits have become important to many engineers not heretofore concerned with such matters. The relay circuit has taken over, in recent years, many tasks formerly performed by the human hand or the mechanical cam and lever. This is evidenced in almost every engineering field. Widespread are the applications of relay circuits to counting, allotting, locating, preferential lockout,[2] and other performances. It is the purpose of this paper to correlate, from a telephone switching system viewpoint, some of the principles and practices involved in one of the most frequently used of the specific circuits, namely, counting. Counting circuits, besides performing their basic function of counting, form the basis for many other circuits of a sequential nature.

Counting Circuit Defined

A relay counting circuit is a circuit arrangement of relays which recognize the appearance and disappearance of electric pulses representing events to be counted, and establish unique conditions during and after each successive pulse, or after a particular number of pulses. The number of preceding pulses, therefore, can be determined by an examination of the combination in which the various relays are operated. A counting circuit usually must perform some external work, and the relays will carry contacts to perform external control functions. In this paper, however, only the means for controlling the action of the counting relays will be considered.

Limitations

It should be understood at the outset that events to be counted by relay counting circuits must be represented by electric pulses having certain characteristics of amplitude, duration, and interval; only events that may be so represented can be counted. The necessary characteristics are quite obvious. The pulse current amplitude must be of sufficient value to operate a relay within the counting circuit. The duration of the operating amplitude of the pulse and the interval between pulses must be sufficiently long to allow a relay to act fully. Thus, the allowable speed of repetition of events to be counted is directly dependent upon the operate and release times of the relays chosen. Presently available, common relays, being electromechanical devices exhibiting both electrical and mechanical inertia, limit the repetition frequency to under 50 pulses per second when directly fed. Transmission of the pulses over long circuits decrease this value because of the pulse mutilation that may take place.

Recognizing a Single Pulse

In order to detect the passage of a single pulse by means of a relay circuit, three distinct conditions must be recognized: pre-pulse, during-pulse, and post-pulse. Obviously these three conditions cannot be detected with a single 2-position relay. Two relays, at least, are necessary to produce a one-to-one correspondence between the three conditions and three unique combinations of the relay circuit. Figure 1 depicts the passage of a single pulse and a sequence of relay operations satisfying the circuit requirements. Here two relays, *A* and *B*, are normal during the pre-pulse condition; relay *A* alone is operated during the pulse, and relays *A* and *B* are operated after the pulse has passed.

A straightforward method of obtaining this action is shown in Figure 2. This circuit employs a pulse-repeating relay *X* to provide a back contact for the control of relay *B*. The pulse, entering on lead *P*, causes relay *X* to operate. Relay *X* operated, causes relay *A* to operate and to lock operated. The termination of the pulse allows relay *X* to release, which now supplies ground through its own back contact, through a contact on operated relay *A*, to relay *B*. Relay *B* operates and locks operated. This arrangement has two disadvantages: an additional relay is required and two relays must act in sequence during and after the pulse.

A second scheme using "shunt-down" operation is shown in Figure 3. The pulse on lead *P* causes relay *A* to operate and lock through its own front contact, but relay *B* is held shunted-down or inoperative by locking ground on one side of its winding and pulse ground on the other. With the disappearance of the pulse, relay *B* operates in series with operated relay *A*. This circuit sometimes is designated a prime pair, since the two relays usually are designated by the same letter, the shunted relay (see Figure 3) being designated the prime (′) relay.

Noninterfering Requirements

These two circuits of Figures 2 and 3 satisfy the original requirements for a

Figure 2. Simple pulse detector

single pulse counter having three distinct combinations, but they do not satisfy two noninterfering requirements that are frequently imposed. These are:

1. The circuit must not permit the back-up of a ground condition to the control (pulse) leads.
2. The circuit must ignore subsequent pulses or grounds on the control lead.

Circuits which satisfy these conditions will find much broader application, since the control lead may be reused for a subsequent control operation after a single pulse. The control lead may be freed from interference by passing it through a back contact of relay *B* in either Figure 2 or 3. Figure 4 shows isolation of control lead *P* of Figure 3.

Alternate Sequence

The above circuits are based on the operating sequence shown in Figure 1. This seems to prove the most satisfactory sequence for a non-interfering single pulse counter. An alternate sequence, shown in Figure 5(A) together with a nonshunting 2-relay scheme, Figure 5(B), based on this sequence, has been worked out. Several disadvantages are at once evident. Here again, the action of two relays in sequence is necessary, producing a slow circuit. The circuit is of the interfering type. Modification by isolation of the control lead *P*, as shown in Figure 5(C), produces pulse clipping to relay *A* which may interfere with locking relay *B* under severe contact stagger.

Pulse Dividers

A requirement might be placed on the 2-relay single-pulse counter that the relays recycle, returning to normal after the completion of a second pulse. One cycle for such a circuit then consists of five intervals, as shown in Figure 6. There are, however, only four unique conditions, the first and last intervals being the same. Circuits which recycle after the second pulse are pulse halvers, more frequently called pulse dividers since, when the input consists of a continuous train of pulses, the relays will act at half speed.

The pulse divider circuit of Figure 7 operates much like the prime pair of Figure 4 in that the first pulse ground on lead *P* causes relay *A* to operate while "shunting-down" relay *B*. The purpose of the continuity transfer contacts on relay *A* is to provide the lead *K* between relays *A* and *B* with an uninterrupted ground, either from lead *P* or from the locking ground, after the start of the cycle. Relay *A* is thereby locked operated and relay *B* held unoperated before lead *P* is opened at this contact. The termination of the first pulse removes the shunting ground from relay *B*, allowing it to operate to the locking ground on relay *A*. Operation of relay *B* extends lead *P* to the junction between resistor *RA* and relay *A* so that the second ground pulse releases relay *A* by shunting action. The continuity transfer on relay *A* again plays the role of securing the pulse ground on lead *K* to hold relay *A* unoperated and relay *B* operated during removal of the locking ground. Relay *B*, now held operated to the ground on lead *P*, releases with the termination of the second pulse, completing the cycle. Resistors *RA* and *RB* are necessary to protect the battery *BB* from direct ground over lead *P*.

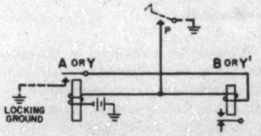

Figure 3. "Shunt-down" or prime-pair pulse detector

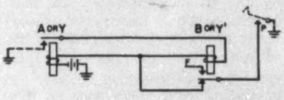

Figure 4. Isolation of control lead after pulse

The circuit of Figure 7 is widely used, where high speed is not essential to the particular application, in automatic telephone switching systems and is commonly called a *W-Z* combination, having been designated so in the first application. The combination has the disadvantage that it is inclined to be slow, particularly on the short-circuit release of the *W* relay.

Open *W-Z* Combination

Where faster operation than that provided by the shunt-type *W-Z* combination is required, the open *W-Z* combination of Figure 8 frequently is employed. It is somewhat faster than the shunt type, since *Z1* usually can be made to operate and release *W* in sequence faster than a single relay can be shunted down. A difficulty sometimes encountered is that the current surge, occurring when the shunt on the winding of *Z* is removed at the end of the first pulse, tends to kick *W* down, releasing the circuit.

Counting a Train of Pulses

The general problem of counting a train of any number of pulses immediately suggests the cascading of circuits such as Figures 4 or 7 to the desired number. It then is evident that the circuit will not only be capable of counting the desired number of pulses, but that it will count a train of any number of pulses less than this maximum. This is because the circuit holds its relays, through its own local circuit, in the combination set by the last received pulse. If, then, no further pulses appear on its input lead, the last set combination will remain indefinitely. As each combination corresponds to the total number of pulses received in the sequence, the number is identifiable.

Action on Maximum Pulses

A counting circuit, having received its maximum number of pulses, may: lock-up during this last pulse and ignore the

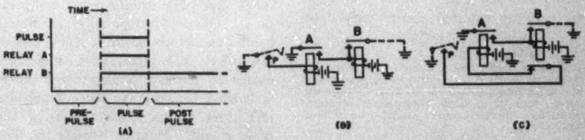

Figure 5. Alternate sequence and circuits for pulse detection

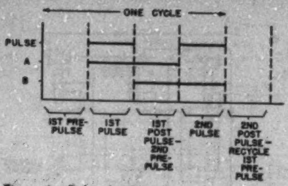

Figure 6. Pulse-divider relay action sequence

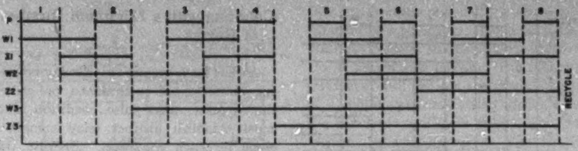

Figure 9. Relay sequence in counting with pulse dividers

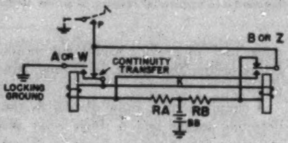

Figure 7. Pulse-divider circuit—W-Z shunt type

termination of this last pulse and any succeeding pulses; lock up at the termination of the last pulse and ignore succeeding pulses; or return all relays to normal on the termination of the last pulse, thus establishing a new cycle which will start the count over on succeeding pulses. The first two cases given are most common, although many circuits recycle part of their total relays.

Counting with Pulse Dividers

A *W-Z* combination counts and recycles on two pulses and, if a train of pulses is applied to the circuit, the *W* and the *Z* relays will act once for each two input pulses. If the *Z* relay then is made to control a second *W-Z* combination and this in turn similarly controls a third, a pulse-counting scheme results. Obviously, the scheme may be extended to count any number of pulses desired. The sequence of operation is shown in Figure 9; the circuit is shown in Figure 10.

One *W-Z* combination recognizes two pulses and recycles, two *W-Z* combinations "count" four pulses and recycle, while three count eight pulses. All relays of the three stages of Figure 10 return to normal at the termination of the eighth pulse. It thus may be seen that *D* pulse dividers of any type will count up to a maximum of 2^D pulses. A circuit using *D* pulse dividers will return to normal and start the count over after the 2^D pulse. If a record of the passage of 2^D pulses is to be retained, at least one more relay must be added to prevent recycling after the 2^D pulse.

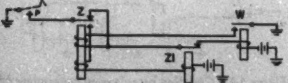

Figure 8. Pulse-divider circuit—open type

The circuit can be easily arranged to cut itself off from the pulse lead for ignoring further pulses after a given number of pulses have been received, if this number is less than the 2^D maximum. This may be accomplished by passing the control lead through contacts of relays which have completed their action following the end of the last desired pulse. For example, after the seventh pulse in Figure 9, the unique condition *W1*, *Z1*, *Z2*, *Z3* relays operated obtains. *Z1*, *Z2*, *Z3* is sufficient to define this interval, and the passage of the control lead through paralleled back contacts on these three relays will open the lead after the seventh pulse.

Two disadvantages are inherent in pulse-divider counting schemes. First, they are slow since, at a number of stages, several relays must act in sequence. For example, during the interval following pulse 2, relay *Z1* must release and *Z2* and *W3* operate in sequence. However, only the first pair of relays, *W1* and *Z1*, are controlled by the pulse and must complete their action during a pulse or interval between pulses. The sequential action of subsequent relays may lag over into the following interval of pulsing without adverse effect, since the control pulse to each succeeding *W-Z* combination doubles in time duration. Where information is used only after pulsing ceases, this is of no particular disadvantage, but where information must be obtained while pulsing is in progress, the arrangement may not be satisfactory.

Second, when the number of pulses to be counted is large, a large number of relays must be examined to determine the count at any stage. This means that, in order to close a circuit path during any one interval, a number of contacts are required. In large circuits this number may be excessive.

Prime Pair Counting

The noninterfering single-pulse prime-pair counter is especially adaptable to counting a series of pulses. Since relay *B* of Figure 4 acts after the pulse terminates, it may be utilized to switch the pulse lead without interfering with its own action or interrupting or clipping the length of a transferred control pulse. The transfer springs on relay *B* may be used to extend the control lead, through the front contact marked *F*, onward to a second similar circuit. Thus, a series of these circuits wired as shown in Figure 12 may be controlled in the sequence of Figure 11. This scheme may be extended to count any desired number of pulses *N*, and will automatically disregard any pulse after pulse *N*.

Various modifications of the basic circuit of Figure 12 may be made to satisfy special applications. For example, the *N'* relay may be required to close an external circuit at the termination of the *N* pulse under one condition or the *N-1* pulse under a second condition. If then

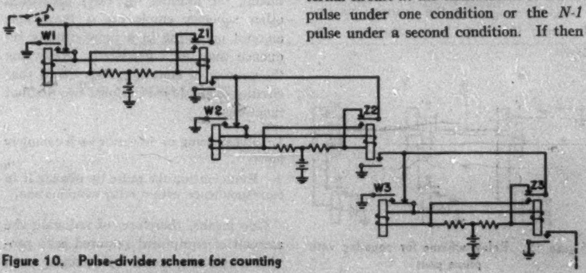

Figure 10. Pulse-divider scheme for counting

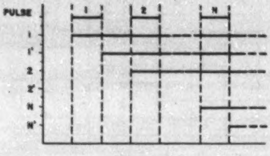

Figure 11. Relay action sequence for counting with prime pairs

the control lead is switched by external means to the armature spring of relay *2'*, as shown by dotted *X* wiring, the *N'* counter will be actuated when the *N-1* pulse terminates. This is a convenient arrangement when some function must be performed after a given number of pulses, and the number of pulses is variable but known in advance.

In Figure 12 each pair of relays is held operated by ground from a make on the nonprime relay. In order to release the relays, this ground must be removed by control means not shown. In Figure 13, the circuit is rearranged so that each pair of relays is released by the action of some higher numbered relay. In this case only one pair of relays remains operated after any given pulse. The last pair must be released by external means. It should be noted in this case that the pulse lead enters the controlling chain of contacts on the prime relays at the *N'* relay rather than at the *1'* relay of Figure 12. This modified circuit acts in the same sequence as that of Figure 12, but has the advantage of checking that all relays are normal before the first relay may act. Figure 12 may be modified to carry this reverse chain of contacts.

Many other variations of the prime-pair counting scheme are possible. For instance, the circuit may start with all relays operated by external means and locked under control of the prime relays, and permit the pulsing to release the relays successively, as shown in Figure 14. Such circuits may be more adaptable for connecting a group of external circuits, then opening the connections one by one, than for basic counting purposes.

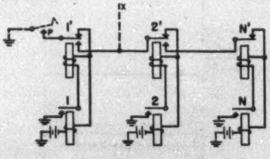

Figure 12. Relay scheme for counting with prime pairs

Counting with a Minimum Number of Relays

As has been mentioned, a relay counting circuit must recognize a pre-pulse, during-pulse, after-pulse condition, and must establish distinct relay combinations for each condition. Because the pre-pulse interval of every pulse except the first overlaps the after-pulse interval of the preceding pulse, the number of intervals required and, hence, the number of necessary relay combinations is $2P+1$, where P is the number of pulses. If, however, the circuit is allowed to lock during the last pulse, the last interval may be disregarded and the combination becomes $2P$.

As two relays may be operated in four combinations and three relays in eight combinations, the number of combinations in which N relays can be operated is 2^N. Now, if a circuit is to count a number of pulses, P, a number of relays N, such that 2^N is equal to or greater than $2P$ or $2P+1$, is the minimum required.

Circuits based on a minimum number of relays can be worked out,[3] but usually do not prove practical. Circuits which use a large portion of the possible relay combinations tend to produce large spring loads and complex contact circuits for their own control. Add to this the number of relays which must be examined to determine the count at any stage,[4] and the contact load becomes excessive. A judicial use of the number of combinations possible may, however, provide a very practical circuit for the establishing of a fixed-number pulse counter which loses or opens an external circuit after a particular number of pulses has been received.

Use of Common Relays

Having rejected pulse counting schemes using a relatively large number of the possible combinations of a small number of relays as too drastic a means of minimizing the number of relays necessary, other schemes employing a reasonable amount operating in a more orderly sequence may be considered. Analyzing the process of counting, it is found that circuits so employed perform two distinct functions:

1. Recognizing or detecting each complete pulse.
2. Enumerating the pulse by placing it in correspondence with a relay combination.

One means, therefore, of reducing the amount of equipment required is to provide a common means of detecting each pulse and to provide additional means for recording the count as pulsing progresses.

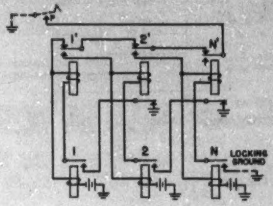

Figure 13. Sequential release of prime pairs

A circuit using a pulse divider as the detecting means and a single relay for recording each pulse is shown in Figure 15. Although the shunt-type pulse divider is shown, the faster open-type pulse divider may be used to advantage in some applications. In tracing the operation of this circuit, it will be found that *Z* operates at the end of the first pulse and grounds the odd lead operating relay *1*. At the termination of the second pulse, relay *Z* releases and grounds the even lead, causing the operation of relay *2*, and so on. Figure 16 illustrates the sequence for the circuit shown, and, also, for the case where relay *W* instead of relay *Z* carries the contact for transferring ground between the odd and even leads. Such circuits are usually called odd and even counters.

Partial Recycling Schemes

In the prime-pair counting schemes of Figures 12 and 13 and the odd and even counter of Figure 15, one prime pair and one relay, respectively, were assigned to each pulse of the count. The amount of apparatus necessary to count *N* pulses can be reduced by reusing these elements after their initial function has been performed. The principle of partial recycling of counting relays can be used to this end. As one example of this principle, consider the prime-pair circuit of Figure 13. In this circuit the operation of each prime

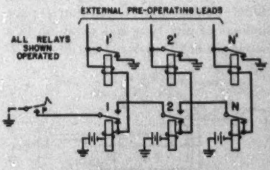

Figure 14. Counting by releasing preoperated prime pairs

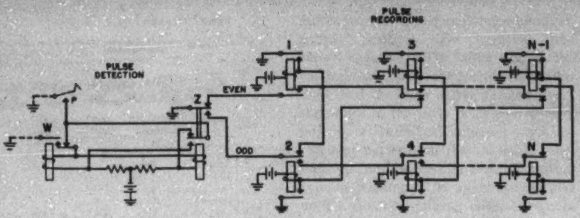

Figure 15. Separation of detecting and recording functions in pulse counting

relay, following the termination of a pulse, releases the preceding pair. After the last pulse, the *N* and *N′* relays are the only ones operated, and the action of the *N′* relay completely disconnects the pulse lead from the circuit. It is a simple matter to arrange this pulse lead, as shown in Figure 17, to make possible the reoperation of the first pair of counters. The sequence of operation is then as follows:

At the end of the first pulse *1* and *1′* are operated.

At the end of the second pulse *2* and *2′* are operated.

At the end of the third pulse *3* and *3′* are operated.

At the end of the fourth pulse *3* and *3′* and *1* and *1′* operated.

Thus, four pulses may be counted by means of three pair of counters or six relays. In extending this scheme, it will be found that ten pulses may be counted by means of 12 relays. Pulses beyond the maximum which may be counted by this scheme are disregarded, operating the unprimed counter of the next-to-last pair during the extra pulse and releasing it at the termination of the pulse.

Other circuits, such as the odd and even counters, also may be partially recycled to achieve economy in apparatus.

Conclusion

Three general types of counting circuits have been discussed and examples of each given. From these examples, which by no means exhaust the available counting-circuit arrangements, it may be concluded that relay counting circuits either are available or may be readily designed for any special application that, from a pulse repetition standpoint, falls within their scope.

In applying these circuits, one of two requirements usually must be satisfied. One requirement will call for the establishment of a condition, after a particular number of pulses has passed, for the control of an external circuit. The other requirement will call for the establishment of a unique condition either during or at the termination of each pulse. The first requirement may be best satisfied by the use of pulse-divider schemes or of circuits where the number of relays is held to a minimum but exceeds the $2={}^{N}2P$ value sufficiently to provide a practical spring load. In these cases the number of relays that must be examined to determine the count at any stage is of no concern. Only one combination is of interest.

The second requirement is satisfied more readily by the prime-pair type of circuit or by the use of common detecting and individual recording form of odd-even counting schemes. The necessity of $2P$ relays of the prime counters or the P plus the common pulse detector relays, may be minimized by the application of partial recycling operation.

Codes and Translations

OSCAR MYERS
NONMEMBER AIEE

ONE of the problems which confronted S. F. B. Morse when he undertook to transmit intelligence by means of his "electric telegraph" was to devise a code suitable to the electrical circuit and mechanical apparatus which he had constructed. His solution was the familiar Morse code. The translators for encoding and decoding the electrical signals were the telegraph operators. Alexander Graham Bell's telephone avoided the need for translations through the use of conversion devices having simple mathematical relationships between the voice signals and their electrical equivalents; but the discrete, arbitrary relationships which characterize code methods have made their appearance in "pulse code modulation" recently devised for microwave transmission. The translators in this case are electronic circuits working at tremendous speeds. This paper, however, deals not with codes and translators for the transmission of the message itself, but with their use in switching systems for the purpose of setting up telephone connections. Here they have been developed in numerous and varied forms, both for sending telephone numbers, or similar information from one central office to another, and also within a central office for signaling from one component of a switching system to another. The forms of the codes and the electrical methods for transmitting them vary with the nature of the information, the form of the apparatus involved, and the character of the signaling channel. This paper describes some of the forms which have assumed importance in the design of switching systems.

Early Codes and Translations

When the first dial switching system was invented one of the basic requirements was a device for coding the called number and apparatus for translating this code into operations of the switching machine. The answers here were the dial and the step-by-step selector.

As the switching art progressed and the nomenclature and trunking problems of large multioffice cities were encountered, it became clear that, although it was desirable to retain the dial because of its simplicity, some recording and translating device other than the 10-level selector, directly controlled by the dial, was necessary at the central office. New groups of circuits, called senders and translators, were therefore introduced for use between the dial and the switches. These circuits were capable of storing the dial pulses and translating them into new electrical codes more suitable for controlling large nondecimal switches.

The first system which used senders and translators was the panel system. These circuits were able to translate the decimal dial pulse code into a nondecimal "revertive" code. (In revertive pulsing the translator presets the sender. The latter then starts the distant selector which, in advancing, sends back pulses which the sender counts. When the predetermined number of pulses has been counted, the sender stops the selector.) The sender also could change part or all of the number into a "call indicator" code for operating a bank of call indicator lamps to give a visual display of the called number at an operator's position in a manual office. Figure 1 is a schematic drawing of the terminating equipment in a panel office to show the background of the revertive pulse code. Selection of a subscriber line through the incoming and final frames requires the translation of the thousands and hundreds digit of the called number into a code which selects one of five banks of terminals (or one of five selector brushes) on the incoming frame, one of four groups on this bank and the selection of one of five banks on the final frame. The selection of a single terminal for the called line on the final bank is per-

formed in two decimal steps called final tens selection and final units selection. It can be seen that the incoming bank selection is a choice of a block of 2,000 consecutive numbers, the incoming group selection is a choice of 500 consecutive numbers, and final bank selection is a choice of 100 consecutive numbers. Table I shows the combinations used in the call indicator code. Three kinds of pulses are used in sequential combination, namely positive, light negative, and heavy negative. The difference in the call indicator code between the thousands digit, and the other digits, resulted from the desire of the early designers to have both revertive and call indicator codes in a common pattern, so that a single relay register could be used for recording either type of pulsing. The panel system also used a d-c key pulsing code, shown in Table II. This was used for registering in a sender the called office designation and number which was keyed from an operator's position. The operator was furnished with a 10-button key set, each button representing one of the ten digits 0 to 9.

Later Examples of Codes and Translations in a Modern Telephone System

Further development of the telephone switching art has resulted in the introduction of what are called crossbar systems. The basic switching unit in these systems is a co-ordinate type of switch (crossbar switch) which is generally controlled by an external circuit. Since these systems require more common controls than the panel system, they employ even more coding and translation in the process of setting up a call. The following paragraphs describe briefly the various successive steps of coding and translating which are used in setting up a telephone

connection in a crossbar system. The examples are presented in the order in which they might be encountered on a normal call.

REGISTERING THE NUMBER THE SUBSCRIBER DIALS

When a subscriber lifts his receiver one of a common group of senders or registers is temporarily attached to his line by switches to record the dialed number. Figure 2 illustrates a typical dial pulse counting and storing circuit of a crossbar sender or register which shows the process of number transformation prior to storage.

A dialed digit in a decimal system consists of a series of line breaks produced by the dial in which the digital value corresponds to the number of breaks (except for zero which is ten breaks) followed by a pause. To register this dialed digit the successive momentary releases of the pulsing relay *L* following the line breaks caused by the dial change the combinations of a group of temporary pulse storage relays, *P1* to *P6*. At the end of the digit there is an interdigital pause which is recognized by a slow to release relay *RA*. The release of this relay transfers the temporarily recorded number to a digit register which will hold it as long as required, and also causes the release of the temporary storage relays and the advance of the steering relays (register advance from which *RA* gets its designation) so that subsequent digits can be directed to succeeding registers. The combinations of the pulsing and temporary pulse storing relays are shown in Table III.

The transformation takes place in two steps. Step 1 is the operation and release of relays *L3*, *L4*, and *L5* which determine whether the pulse is odd or even. Step 2 is the operation of the *P* relays which provide a unique combination for each digital value. The *P* relays close paths to register relays in the "2 out of 5" code. For this code, five register relays per digit are provided, two of which are operated by each combination of *P* relays. The circuit for operating the 2-out-of-5 storage registers is woven through the lower contacts of the *P* relays in a typical "relay tree" to fit the register circuit employed. (A relay tree is an array of contacts on a group of associated relays which are interconnected in a pattern which resembles the branching of a tree.) This contact array is a small translator. If the register relays had been required in different combination, say a decimal code, a corresponding relay tree on the *P* relays would have translated the *P* relay combinations into this code as shown in Figure 3.

TRANSLATING THE OFFICE DESIGNATION

The office designation, when used, consists of the first one, two, or three dialed digits in a local (as distinguished from toll) system. For our example, let us assume a large city with three digit office codes. (A typical code of this kind is ACademy 2.) In such a city when the sender has received three digits it calls for a momentary connection to a marker which is one of a small group of common control circuits. In a fraction of a second, during which it is attached to the sender, the marker operates switches to set up the call to a trunk to the called office and combinations of relays in the sender to control the information to be sent to the called office with regard to type of pulsing, number of digits, and other information which the machine needs to complete its job.

Figure 4 shows, in simplified form, how the marker acts on the coded office designation to obtain the information which the marker and sender need for their subsequent action. Step 1 in the marker is the closure of a circuit to a single point ("code point") which corresponds to the office designation. With three digit designations this is the selection of one out of a thousand possible code points. Step 2 is the operation of a route relay to which the code point is cross-connected and the closure of variably cross-connectable contacts of the route relay to relays which record and check the data contained in the route relay cross-connections.

The operation in brief is as follows: A multiplicity of leads are closed to the marker from the sender by multicontact relays. Two of each of the three sets of five code input leads are grounded by operated register relays in the sender and operate corresponding relays in the marker. One of 20 50-contact relays is operated by the *A* relays and the "above or below five" circuit from the *B* relays. This relay is operated at the same time one of five 10-contact relays is operated by another circuit through the *B* relays. One of the ten paths from the *C* relays is thus closed through the contacts of the operated "tens" relays and "fifties" relay to ground a single code point.

The code point is cross-connected to one of the route relays whose contacts are further cross-connected to provide the desired information. As an example of the kind of information furnished, the route relay locates the busy test leads of the called group, determines the type of outpulsing and the number of digits to be sent, as well as several other miscellaneous items.

SENDING TO THE TERMINATING OFFICE

A sender may be arranged to complete to several types of connecting offices. Assume that the sender under consideration is equipped to outpulse either multifrequency pulses or decimal pulses, or that it can signal the trunk to cut through with no pulsing. Assume further that the connecting office in this example is arranged to receive multifrequency pulses. (Multifrequency pulses are short spurts of pairs of frequencies in the voice range.) Since, as indicated previously, each digit register has two out of five relays operated, and since multifrequency pulsing is based on the same 2-out-of-5 code (as shown in Table IV), once the marker has indicated that multifrequency pulsing is required, it is merely necessary for the outpulsing control circuit of the sender to steer from digit to digit sending out the multifrequency pulses, each pulse consisting of two frequencies, corresponding to the operated digit register relays. The pair of frequencies for a digit are sent simultaneously and successive digits follow each other with a momentary open period between pulses.

PULSE COUNTING RELAYS
PULSE GENERATOR
TO STOP PULSING RELAY

Figure 5. Translation of 2-out-of-5 registration to dial pulses

If the connecting office had been of the dial pulse receiving type, the outpulsing part of the sender circuit would have reversed the translation originally employed in registering the dialed digits. One method of doing this is shown in Figure 5. Here the relay-tree contacts are woven through the 2-out-of-5 register group to mark a stopping point in a chain of counters which can count ten pulses. Each pulse, of course, results in a line break to the equipment ahead, and a timed interdigital pause also is provided.

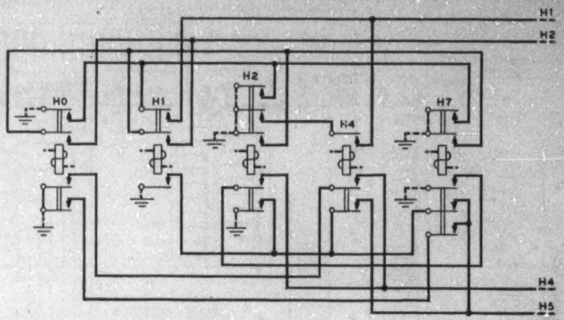
Other types of "in" and "out" pulsing also are available in the crossbar system. Revertive pulsing is provided to reach panel offices. D-c key pulsing is employed between operator positions and senders. However, broadly speaking, the basic design of the sender is the same for all types of pulsing. It consists of three parts:

1. A group of register relays which record the incoming pulses.

2. Tree circuits from the registers to prime the outpulsing relays.

3. A group of pulse generating elements (relays or oscillators or frequency generators) and control relays which cause the circuit to advance from digit to digit as required.

Figure 6. Relay tree for translation of 2-out-of-5 code into 4-relay code



Another interesting case where the coded digits are converted back to verbal pronouncements, is the "call announcer" method of completion to manual offices used as an alternative to the call indicator mentioned before. Here again the pattern outlined is followed. The generator of the outgoing information in this case, however, is a group of rotating films with voice tracks for each digit and the four station letters. The films are selected through the relay trees of the registers

Receiving the Number at the Terminating Office

Multifrequency pulsing is employed in the latest type of central offices to transmit the called number to the terminating office. At the terminating office the signals are detected by a multifrequency receiver consisting of filters and vacuum tubes, and then stored on a relay register in the terminating sender of which the receiver is a part. The transfer of the number from the receiver to the register does not involve translation. However, before the called subscriber's bell can be rung a major translation is required. This results from the fact that the subscriber is called by his directory number, whereas the location of his line equipment bears no relationship to this number, being determined instead by other factors, such as traffic and class of service. This translation is performed by a terminating marker to which the terminating sender connects for a fraction of a second. The actual translation is rather complicated since it is, in fact, a number of translations. For example, in addition to locating the line equipment, the directory number also must be analyzed to see if it is one of a *PBX* group, whether the number is a working number, and if so, if it is also a free line or a coin line. In addition, of course, the ringing code must be determined if the call is for a party line.

Table IV. Multifrequency Code

Digit	Relay Combination	Frequency Combination, Cycles
0	4+7	1,300+1,500
1	0+1	700+900
2	0+2	700+1,100
3	1+2	900+1,100
4	0+4	700+1,300
5	1+4	900+1,300
6	2+4	1,100+1,300
7	0+7	700+1,500
8	1+7	900+1,500
9	2+7	1,100+1,500

Table V. Translation of 2-Out-Of-5 Code into 4-Relay Code

Digit	2-Out-Of-5 Relay Combination	Terminating Marker Relay Combination Thousands	Terminating Marker Relay Combination Hundreds, Tens, Unit
0	4+7	none	none
1	0+1	1	1
2	0+2	2	2
3	1+2	1+2	1+2
4	0+4	4	4
5	1+4	1+4	5
6	2+4	2+4	1+5
7	0+7	1+2+4	2+5
8	1+7	8	1+2+5
9	2+7	1+8	4+5

Briefly, the action is as follows: the multifrequency pulsing receiving circuit which is part of the terminating sender circuit receives the pulses transmitted over the trunk from the originating sender (or keyset, in some cases) in the 2-out-of-5 combinations listed previously, and stores this information on groups of relay registers through a relay steering circuit which advances after each digit. These registers are equipped with contacts to translate the 2-out-of-5 code into the code required by the terminating marker to which the number is transferred when complete. The translation consists of a change from 2-out-of-5 relays to "marks" or grounds on a set of four leads for each digit in combinations varying from "no leads" grounded for the digit "O" to "three leads" grounded for the digit "8". The translating tree on the digit registers is somewhat unusual in that it consists only of make contacts as illustrated in Figure 6. Errors caused by trouble conditions are checked both in the receivers and in the markers. The combinations to which the sender registrations are converted are shown in Table V. It will be noted that the thousands digit is different from the hundreds, tens and units. This is one of the cases where the coding has been designed to fit the connecting systems, and results from the fact that the terminating marker also works with revertive pulsing senders where the revertive pulse combinations fall into this pattern.

This pattern also fits the call-indicator pulse combinations which at one time were pulsed into a receiving circuit with a register for both call indicator and revertive pulses.

When the terminating sender or register has received a full complement of digits, it makes a momentary connection to a terminating marker, and transmits to it the called number in the code of Table V. The translation is somewhat different than in the originating marker, however. It is not economical to provide a route relay per line per marker. A compromise is employed instead. The four numerical digits consisting of thousands, hundreds, tens, and units are reduced to a "code point group" of terminals for a block of consecutive numbers. One of the functions of this set of terminals is to select one of a group of auxiliary circuits called "number groups." Each number group of several hundred directory numbers is subdivided into smaller directory number groups which the marker also selects. A final operation selects the called line, if it is idle.

As stated previously, the function of the number group is to provide a circuit where the contacts and cross-connections per line for translation can be provided once per office rather than to furnish a set per marker which, in a large office, might mean as many as ten sets. Selection of a set of contacts in the number group is similar in principle to the operation of a route relay described previously and results in the operation of relays in the marker which provide line locating information and the ringing code. The terminating marker sets up the connection in the called line and then puts itself back to circulation for handling other calls.

At the present time the Bell Telephone System is extending automatic switching to its toll plant. The problems met in this connection have in general, been solved by an extension of the coding and translating mechanisms already employed in the local crossbar systems. Future development of switching systems will undoubtedly be accompanied by improvements in translators which are becoming an increasingly important part of the control mechanisms.

No Discussion

Loss Measurements Made on Underground-Cable Overhead-Conductor 132-Kv Transmission Line at Carrier Current Frequencies

H. A. CORNELIUS
MEMBER AIEE

B. WADE STORER
ASSOCIATE AIEE

Synopsis: This paper discusses carrier current applications on a 132-kv line composed of underground cable and overhead conductors. The discussion includes some of the test procedures used at the carrier frequencies in measuring the losses in the various components of the circuit and some of the difficulties encountered. The measured results are compared on a decibel loss and on a watt loss basis. Some data on "ambient" noise levels and on signal to noise ratios also are included.

THE Commonwealth Edison Company of Chicago and the Public Service Company of Northern Illinois have an interconnecting 132-kv power line over which it is desirable to place a reliable carrier transmission channel for relaying and other purposes.

This particular line, which is roughly 37 miles in length, extends from Northwest Station in Chicago to Station 6 in Waukegan, Illinois. Although the line is not long, it presents many troublesome carrier problems. A single-line schematic diagram of the line is shown in Figure 1.

TROUBLESOME FACTORS IN THE APPLICATION

The carrier channel difficulties arise chiefly from the 5.8 miles of 600,000-circular-mil paper-insulated oil-filled lead-covered cable extending out from Northwest Station. This length of cable would not be particularly difficult were it not for the fact that it is equipped with sheath bonding transformers. These are used to reduce 60-cycle circulating currents in the sheaths, thus avoiding decrease in the cable load capacity. The sheath bonding transformers present a high loss return path to carrier frequency currents.

Adding to the carrier problems are the increased terminal equipment losses at Northwest Station. These losses are greater than for an overhead line terminal, due to the fact that the carrier energy is fed into the low impedance cable. The test results at Northwest Station show that about 71 per cent of the available carrier energy (at 75 kc), is lost in the terminal equipment before reaching the 132-kv cable.

Other factors that contribute to the carrier transmission losses are: the cable-overhead conductor mismatch at the Chicago city limits (see Figure 1); the line tap at Skokie Substation; the normal overhead conductor attenuation; and the carrier terminal equipment loss at Station 6 in Waukegan.

Losses and changes in attenuation also result from two other 132-kv lines that parallel the overhead section, and normal line noise is increased by an electric railway on the same right-of-way with the 132-kv line.

DIFFICULTIES ENCOUNTERED IN MAKING LOSS MEASUREMENTS

1. External conditions, such as pick-up from nearby broadcasting stations, and noise produced by the paralleling electric railroad mentioned before.
2. High residual currents, in the cable section and in the overhead section resulting from coupling to other 132-kv lines on the same right-of-way.
3. Difficulty in procuring adequate line outages for the tests at the time they were being conducted.
4. Lack of good communication facilities between the cable-overhead conductor junction and the line terminals.

LOSS MEASUREMENT PROCEDURE

The carrier loss measurements were divided into three general parts: the terminal equipment; the cable section; and the overhead section. The mismatch loss at the cable overhead junction was calculated from the impedance measurements made on the cable section and on the overhead section. The 200-foot line tap loss at the Skokie Substation was assumed to be three decibels. The test methods are shown in detail, and some calculations are included in an attempt to clarify decibel loss values for those reading this paper who may not be familiar with this method of loss evaluation.

Terminal Equipment Losses

NORTHWEST STATION

Wave Trap Loss. The impedance of the wave trap at the present operating frequency (75 kc) is 3,700 ohms. Since this high impedance in parallel with the low-impedance 132-kv cable produces very little loss, this small loss has been ignored at the Northwest terminal of the 132-kv line.

Coupling Capacitor and Drain Coil. The coupling capacitor plus drain coil loss, R_s (see Figure 2), was found by substituting a variable resistance and a variable air capacitor in a Q circuit. The upper end of the coupling capacitor was grounded, and the drain coil in the base

Figure 1. One line diagram of underground cable overhead-conductor 132-kv line and diagram of cable sheath connections

of the capacitor was left in place during the tests.

The results obtained from the measurements are as follows:

Frequency in Kilocycles	50	75	100	150
R^s in ohms	36	30	26.5	22.5
Loss in decibels	3	2.8	3.0	3.2

The decibel loss remains approximately constant with increase in frequency. This is due to the fact that the cable input resistance declines at about the same rate that the coupling capacitor plus drain coil loss, R_s, declines.

Lead-in Wire. The lead-in wire from the coupling capacitor to the line tuning unit is 50 feet long. It is a weatherproof wire, supported by three post-type 33-kv insulators.

To obtain the loss in the lead-in wire only, a "no loss" air capacitor was substituted for the 132-kv 0.001 microfarad coupling capacitor, as shown in Figure 3. In addition, another circuit containing a variable air capacitor and a variable non-inductive resistor was used to determine the total power input to the lead-in circuit.

The method of procedure was to read I_s and I_c. A dummy load was then substituted by adjusting C_{as} and R_a to give the same current reading on I_s, as was obtained previously with C_a and R_c in the circuit. With these values and the cable input resistance (R_c) known, the loss in the lead-in wire was calculated from the ratio of the total power input to the power delivered to the cable. At 75 kc:

Power into lead-in wire:
$I_s^2R_a=0.38^2\times36.9=5.45$ watts
Power out of lead-in wire:
$I_c^2R_c=0.294^2\times33.2=2.87$ watts

$$\text{Lead-in loss}=10\log\frac{5.45}{2.87}=2.8\text{ decibels}$$

The result obtained, plus the cable input resistance measured were then used to calculate the equivalent resistance of the lead-in circuit, as follows:

$$\text{Loss}=10\log\frac{R_1+R_2}{R_2}$$

$$2.8=10\log\frac{R_1+33.2}{33.2}$$

$$10.28=\frac{R_1+33.2}{33.2}=1.905$$

$$R_1+33.2=1.905\times33.2=63.24$$
$$R_1=63.2-33.2=30.0\text{ ohms}$$

Figure 4 shows the equivalent loss circuit of lead-in, air capacitor, and cable.

The decibel loss (at 75 kc) to be expected in the lead-in circuit when the 0.001-microfarad coupling capacitor is used instead of the "no loss" air capacitor, is as follows:

$$\text{Loss}=10\log\frac{R_1+R_2}{R_2}=10\log\frac{30+63.2}{63.2}$$

$$=10\log\frac{93.2}{63.2}=10\log 1.48$$

$$=1.7\text{ decibels}$$

Figure 5 shows the equivalent loss circuit of lead-in, coupling capacitor and cable.

The results obtained in the lead-in wire circuit at four different frequencies are summarized as follows:

Kilocycles	50	75	100	150
Decibels measured in test circuit	2.8	2.8	2.6	2.7
Equivalent resistance in ohms	31.7	30.0	22.2	17.7
Decibel loss in normal circuit	1.6	1.7	1.5	1.5

LINE TUNING UNIT. The full resistance of the large 300-turn transmitter tuning coil in the equipment tested varies from 21 ohms at 50 kc to 60 ohms at 150 kc. The Q increases from 91 at 50 kc to 113 at 150 kc. At 75 kc, for the portion of the coil used, the resistance is 22.5 ohms and the Q is 57 (between taps 3 to 180).

WAUKEGAN STATION

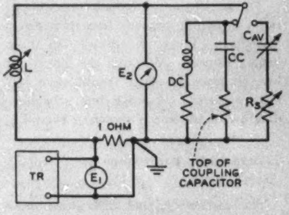
Using the methods described previously the Waukegan terminal losses were found to be as follows:

Kilocycles	50	75	100	150
Decibel loss	3	3	2	2

132-Kv Cable Section Loss Measurements

The characteristic impedance, the resistance component of input impedance and cable attenuation were measured on the cable section. The methods used and results obtained are given below. The test circuit was arranged as shown in Figure 6.

Characteristic Impedance: The characteristic impedance, Z_o, of the cable was determined by reading the current and voltage input to the cable with the far end



L
E2
DC
CC
CAV
RS
1 OHM
TR

E_2 = vacuum tube voltmeter
CC = coupling capacitor
DC = drain coil
C_{as} = variable air capacitor
R_s = variable resistor

of the cable open circuited to give Z_{oc}, and with the far end of the cable short circuited to give Z_{sc}. Z_o was then calculated from the relation

$$Z_o=\sqrt{Z_{oc}Z_{sc}}$$

The loss in the cable was so great that no measurable difference was found between the open circuit and short circuit impedances.

The results are as follows:

Frequency in Kilocycles	50	75	100	150
Characteristic impedance	42.5	38.2	28.5	31.0

Input Resistance, Impedance, and Attenuation. The test procedure was as follows: The transmitter was tuned to maximum output into the cable, and the current I_1, and voltage E_1 were read. Because of the high loss mentioned previously in this cable, the transmitter loading was not affected by change in the terminating resistance R_2. To obtain the input resistance, therefore, it was only necessary to substitute the dummy load R_1, retune C_{av} and adjust R_1 to give the same I_1 reading. These steps gave the input impedance and input resistance

$$Z_{in}=\frac{E_1}{I_1}(R_{in}=R_1)$$

In order to obtain the minimum attenuation at each frequency in the cable, it was necessary to find the proper terminating resistance. This was done by varying R_2, reading E_2, for each value of R_2 over a reasonable range and then plotting the power absorbed from the cable for each setting of R_2. The maximum value of absorbed power (taken from the curve plotted) gave the proper terminating resistance, R_2, for the cable. The attenuation was then obtained from the ratio of the power input into the cable ($I_1^2R_1$) to the power received for this value of R_2, (E_2^2/R_2).

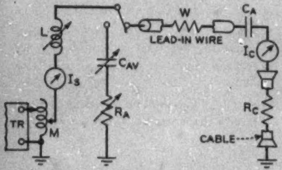

Figure 3. Lead-in wire test circuit

R_c = cable input resistance
C_{av} = variable air capacitor
R_a = variable noninductive resistor

$$\text{Attenuation}=10\log\frac{I_1^2R_1}{E_2^2/R_2}\text{ decibels}$$

The results are shown as follows:

Frequency, Kilocycles	Z Input, Ohms	R Input, Ohms	Attenuation, Decibels
50	42.5	35.0	25
75	38.2	33.2	29
100	28.5	27.0	36
150	31.0	20.5	53

Overhead Section Loss Measurements

The losses measured in the overhead section of the line, including the cable-overhead conductor mismatch loss calculations, are given below:

Overhead Conductor Losses: Using the above test methods, the losses in the overhead conductors between the Chicago city limits and Waukegan Station were measured.

Results obtained are shown as follows:

Frequency in Kilocycles	50	75	100	150
Decibel loss	4	5	6	9

It was found impossible to stop reflections on the overhead conductor section by terminating the line in a single resistance. At 75 kc, a minimum value of reflections was found by terminating the line in 435 ohms. Further tests on the overhead section are needed to complete this portion of the loss data.

Cable-Overhead Mismatch Loss. Looking from the 33-ohm cable section (at 75 kc) into the 435-ohm overhead conductor section, the mismatch loss at this frequency can now be calculated.

The cable may be considered as a generator having open circuit voltage E and internal resistance, $R=33$ ohms. The power transfer to the 435-ohm load would be

$$P_2=I^2435=\left(\frac{E}{33+435}\right)^2\times 435$$

$$P_2=\frac{E^2}{504}$$

Figure 7 shows the circuit used to calculate cable-overhead mismatch loss.

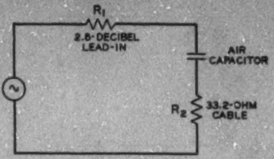

Figure 4. Equivalent loss circuit of lead-in, air capacitor and cable

For 100-watt transmitter (*TR*)

$$I^2R = 100$$

$$I^2 = \frac{100 \times 10^{-6}}{28.69} = 3.485 \times 10^{-6}$$

$$I = 1.87 \text{ milliampere}$$

one half the carrier power would be absorbed at the Skokie Substation carrier set. This would be a 3-decibel loss in the Northwest to Waukegan carrier transmission.

Summary of Losses

A calculation and summation of the various losses along the line at 75 kc in transmitting carrier energy from Northwest Station to Waukegan Station is given in Figure 9. The losses are shown in decibels and in watts. The resistance values also are given in Figure 10 for a hypothetical series circuit that would deliver a current at the receiving end at Waukegan Station of the measured value.

In the circuits shown in these figures the overhead section of the line is terminated in 435 ohms resistance. Since the Waukegan Station terminal equipment loss, at the frequency for which the analysis is made, is three decibels, approximately one half of this resistance appears in the terminal equipment and the other half in the resistance load (R_T).

Signal-to-Noise Ratio Measurements

Signal plus noise and noise measurements were made at Northwest Station, Skokie Substation, and Waukegan Station, using a standard noise meter and a specially-designed converter unit to lower the frequency range of the noise meter to the 50-150 kc carrier band.

For these measurements the present carrier coupling capacitor was tuned at each location by means of a low-loss coil into a resistance load. A 500-ohm termination was used at Skokie Substation and Waukegan Station, and an 85-ohm termination was used at Northwest Station (coupling capacitor and lead-in 30 ohms each and line tuning coil 25 ohms). Since the noise power received was less than 10 per cent of the signal power, the signal plus noise readings were assumed to be signal power only.

The following signal-to-noise ratios were obtained on a clear, dry day at 75 kc:

Northwest = 314 to 1
Skokie = 105 to 1
Waukegan = 74 to 1

At the time the 74-to-1, (37 decibels) signal-to-noise ratio test was made at Waukegan, the noise power measured in the 500-ohm termination was 0.15 microwatt.

Assuming a 100-watt 90-decibel range, 75-kc transmitter-receiver carrier set were applied to the line, the following conclusions could be drawn for the 74-to-1 signal-to-noise ratio.

Minimum receiver power required, P_2

$$10 \log \frac{100}{P_2} = 90$$

$P_2 = 10^{-7}$ watts = 0.1 microwatt

Signal power, P_s, received at Waukegan through 51.2 decibels attenuation (see Figure 9)

$$10 \log \frac{100}{P_s} = 51.2$$

$P_s = 758$ microwatts

Noise power in 217.5-ohm termination, P_n

$$P_n = \frac{217.5}{500} \times 0.15 = 0.065 \text{ microwatt}$$

Signal-to-noise ratio would be

$$\frac{P_s}{P_n} = \frac{758}{0.065} = 11{,}660 \text{ or } 40.7 \text{ decibels}$$

These data show the noise power to be so low on a dry, clear day that it could hardly interfere with receiver operation.

To show the range available for the postulated conditions, it is assumed that

the receiver would function satisfactorily on a 1.5-to-1 signal-to-noise ratio (0.1/-0.065 microwatt). With 90 decibels range carrier equipment, less the 51.2 decibels measured for the over-all line attenuation, 38.8 decibels is left to provide for changes in noise or signal power.

On the other hand, if it is assumed that the received signal power must be ten times the measured noise power (0.065 ×10 or 0.65), then the available receiver operating range would be:

$$\text{Decibel range} = 10 \log \frac{758}{0.65} = 10 \log 1{,}166$$

$$= 30.7 \text{ decibels}$$

In conclusion, sufficient data have not yet been obtained on signal-to-noise ratios under severe weather conditions. However, measurements made to date during light rains and snow conditions, indicate that the signal-to-noise ratios will permit securing a reliable carrier channel over this line.

No Discussion

Automatic Range-Adjusting Radiosonde Recorder

GEORGE E. BEGGS, JR.
ASSOCIATE AIEE

A RADIOSONDE is the air-borne unit of an air-to-ground telemetering system. This equipment transmits audio frequencies in time sequence which represent temperature and humidity, and a fixed reference signal. These signals constitute frequencies produced in the relaxation oscillator circuit of the transmitter, covering a range from 8 to approximately 200 cycles per second. A commutating switch, operated by an aneroid pressure cell, transfers the input terminals of the oscillator circuit from the temperature measuring element, to the humidity measuring element, to the reference signal circuit, in a definite sequence. Since the switch is actuated by an aneroid cell, each step of the switch represents a change of altitude. Thus temperature and humidity data are referred to altitude.

Air-borne radiosonde equipment, being of necessity lightweight, expendable, battery operated, and subject to wide variations of temperature, pressure, and humidity during balloon ascent, is subject to certain calibration drifts, exclusive of changes in primary measuring elements. The "reference frequency," transmitted periodically between indications of temperature and humidity, indicates the magnitude and direction of such drifts. Since this reference frequency drifts in the same proportion as the drifts occurring in the other indications, it has been used in the past as a secondary standard for manual range-readjustment of the recorder at the ground station. These frequent range changes, and the need for check calibration tests of ground equipment from time to time, demand skilled personnel in constant attendance.

Early recorders, used to record the audio frequency signals transmitted from an air-borne radiosonde, were primarily strip-chart single-range frequency recorders. Under a development contract between the Signal Corps Engineering Laboratories, Belmar, N.J., and the Leeds and Northrup Company, a recorder has been developed which performs automatically the functions of range-adjustment and calibration. Many of the features incorporated in this equipment represent joint efforts of the two organizations.

This radiosonde recorder includes a 10-inch strip chart covering the range 0 to 200 cycles per second; a frequency meter which converts incoming frequency, over the range from 8 to 200 cycles, to direct current proportional to frequency, in a linear fashion; a frequency standard with a limit-of-error of 0.01 per cent, or better, for automatic calibration and linearity checks, and a control panel having circuits for automatic range-adjustment of the recorder in accordance with the reference-frequency signals received. Drifts occurring in the airborne transmitter are cancelled out by this range-adjustment, resulting in corrected indications for temperature and humidity. An over-all limit-of-error of ±0.25 per cent, or better, is obtained, including the automatic, range-adjustment feature, the operation of frequency meter circuits, and automatic relay switching at the control panel.

Ease of service and maintenance, compactness, and convenience are secondary, but important, features. All units are designed for standard 19-inch relay rack mounting, each unit sliding into place in the rack and making connections automatically to the rack circuits as it is fastened in place, through the use of multiple-contact connectors. In some cases, as many as 60 connections are made when a unit is plugged in. A-c and d-c power and measuring circuits of various levels are carried in these connectors.

Complete System

The complete recorder, as shown in Figures 1, 3, and 4, comprises input switching and selector circuits followed by the frequency meter. The frequency meter is followed by a null-balance, potentiometer recorder with a full-scale range of approximately 20 millivolts. This full-scale range is variable by approximately ±15 per cent of nominal full-scale range, by either manual or automatic means.

The control panel includes relay and control circuits for automatic range-adjustment; for selecting appropriate input signals; for operation of the automatic stepping-switch of the frequency standard; for counting the number of automatic calibration sequences which have occurred; means for aural monitoring of incoming frequencies, and indicating instruments for observing line voltage and frequency.

The complete recorder is intended for use with standard air-borne radiosonde equipment, and new types under development. Battery voltage changes or temperature effects on the components of the radiosonde affect all signals of temperature, humidity, and reference in the same proportion. Accordingly, if the recorder is readjusted to read at the same chart position for each succeeding reference signal received, then temperature and humidity readings will be corrected for

Yetter (formerly of Leeds and Northrup Company) of Sun Physical Research Laboratory, for development of the frequency meter circuits; to W. R. Clark, David Clements, A. W. Kozak, and A. J. Williams, Jr., for advice and assistance in design and fabrication of this equipment.

drifts in their actual transmitted frequencies, assuming that the primary measuring elements themselves are correct.

The signal from the radiosonde transmitter is received by a radio receiver with its output circuit connected to the input circuit of the frequency meter. The corresponding d-c voltages produced by the frequency meter then cause the recorder to indicate these values on the chart. No signals above approximately 175 cycles are produced for any temperature or humidity condition. On the other hand, all reference signals utilized for range-adjustment of the recorder occur above 175 cycles. A recorder control cam (*B* cam) closes a relay circuit any time the recorder balances above nominal 175 cycles, thus recognizing the presence of a reference signal. This activates the automatic-range-adjustment circuits, causing the recorder to readjust its range. All reference signals are made to indicate 190 cycles on the chart by varying the slidewire voltage, until the d-c voltage corresponding to the incoming signal, and a tap point on the slidewire representing 190 cycles (95 per cent of full scale), are of equal value. This is the corrected, reference-point indication, resulting in corrected humidity and temperature indications. The 190-cycle value is used since this is the nominal value of the reference signal. The actual method of performing this function will be described briefly under the heading Control Panel.

Frequency Meter

The frequency meter is the heart of the system. Figure 2 is a block diagram of this unit. Incoming frequencies are amplified in a high-gain multistage, vacuum-tube amplifier and clipped so that square waves are produced from any incoming wave shape, independent of amplitude, within wide limits. By differentiation of these square waves in a resistance-capacitance circuit of very short time-constant, sharp positive and negative pulses are produced. An overbiased amplifier disposes of the negative pulses, allowing the positive pulses only to continue through the system.

These positive pulses, occurring at a rate determined by the incoming frequency, are then used to initiate the operation of a "one shot" multivibrator. This circuit produces a positive pulse of fairly constant width and height regardless of the shape of the incoming pulse, but the repetition rate of the pulses of this circuit is still dependent upon the original incoming frequency.

The pulse derived from the 1-shot multivibrator is then fed into a delay line, having a total delay of approximately 100 microseconds, from the input terminals of the line to the short circuit termination of the line and back to the input terminals of the line.

The delay line construction, shown in Figure 8, is comprised of an inductance-capacitance-type filter circuit in which mutual inductance is present between the adjacent coils to improve band-width of the circuit. This mutual inductance is determined by the amount of overlap between the coils, the overlap being determined by the slope of the mounting pieces.

The coils are connected in series, with shunt capacitors to ground, each coil and capacitor combination being mounted on a separate mounting form. The complete delay line comprises 30

filter sections which are mounted in a sealed container.

The bandwidth of this delay line is made sufficient to prevent the pulse shape from being altered appreciably during its transmission down the line and back. This passive network determines the delay between the incoming positive pulse and the outcoming phase-inverted, or negative pulse, the time delay being fixed in value. The new, negative pulse produced in this fashion is inverted to become a second positive pulse. Then both positive pulses, now forming a pair of positive pulses separated by 100 microseconds, the pairs occurring at a repetition rate still determined by the incoming frequency, are amplified and applied to an output "flip-flop" circuit in such a manner that the first pulse turns the circuit on, and the second pulse turns it off, through control tubes.

Accordingly, in the cathode of the output stage a pulse is produced with its width determined by the time spacing between the two pulses in a pair, and its repetition rate determined by the incoming frequency.

The height of the output pulse is determined by the tube constants, the tube-heater temperature, and the plate-supply voltage. The plate-supply voltage is regulated by a vacuum-tube voltage-regulator circuit. In addition, the output-stage cathode temperature is maintained sufficiently constant by the inclusion of the heater of the output stage in the load circuit of the power supply. The use of a cathode-follower makes variation of tube constants relatively unimportant over a fairly wide range, as far as height of the output pulse is concerned.

Figure 3. Front view, radiosonde recorder, reroll table in writing position

These output pulses, essentially of the same height and of the same width, as determined by the passive delay line network, are averaged in a filter circuit which removes the a-c component, leaving a d-c voltage proportional to the incoming frequency. The output voltage of the filter circuit is measured by a potentiometer recorder. To minimize the error of the system, the potentiometer recorder circuit is modified so that the power supply for the slidewire, instead of being a battery, is obtained from the same plate, supply line as is used to operate the output cathode-follower stage. Therefore, any variations in the output voltage of the regulated power-supply are cancelled out, because the recorder measures the ratio of the output voltage of the frequency meter and the slidewire voltage, both of which vary in a like fashion.

The output filter has an appreciable time constant. To prevent disturbances from reaching the slidewire prior to reaching the output stage, the same time constant is included in both circuits.

To allow adequate full-scale speed of the recorder, the time constant of the output filter must be short enough so that it will not restrict the rise-time of the d-c voltage to a time longer than the full-scale recorder time desired. On the other hand, it is necessary that the output filter have sufficient time constant to prevent the lowest frequency being recorded introducing any a-c component into the output of the filter. This is not too difficult to accomplish, if the two limits are not too close to each other. In this system, stable recording is obtained to less than eight cycles per second input frequency, with a full-scale recorder-speed of approximately three seconds.

Recorder

The recorder comprises a modified Leeds and Northrup model *G* electronic instrument. The modifications are primarily mechanical. The recorder has been designed for relay rack mounting with file drawer type construction of the recorder proper, to improve accessibility for paper loading and pen service. The standard model *G* amplifier, including a vibrator-type converter, and amplifier stages, has been modified to allow mounting in a rack with plug-in features. The chart reroll device is of the type which can be swung back into a storage compartment giving a flush front recorder, or may be swung out and used as a writing table.

This reroll table includes a "window shade" type of roller mechanism with a solenoid-operated clutch, providing for examination of up to six feet of prior record by lifting the paper and pulling it out for examination. The paper will return to the storage compartment in the same manner as a window shade, following which normal reroll drive is activated by closure of a microswitch operated by paper tension. Hand advance of the paper can be accomplished by a knob on the reroll table, when desired.

Forty yards of paper are accommodated in the recorder and reroll table with a paper advance speed of one-half inch per

minute, allowing about 48 hours of continuous recording.

Frequency Standard

In addition to the signals derived from the incoming radio signal from the radiosonde transmitter, signals also are available from an internal frequency standard which produces frequencies of 190, 160, 140, 120, 100, 80, 60, 40, 20, and 10 cycles with limit-of-error of 0.01 per cent, or better. This frequency standard, supplied by American Time Products, Inc., utilizes two hermetically-sealed low-temperature-coefficient tuning forks. Multivibrator circuits used with these forks produce the frequencies noted. These frequencies are selected by a stepper switch of the telephone type, operated either automatically or manually, for field check of the linearity of the recorder. Accordingly, the frequency standard acts as a primary standard for field use.

Other Input Sources

In addition to the radiosonde signal and the frequency standard signals, two other signal sources are provided for quick check of recorder operation. Both 60 cycles and 120 cycles are derived from the incoming line supply by tapping off a portion of filament supply in one of the units, and by full-wave rectification of this supply. These frequencies are available at the input selector switch on the main control panel, as are the frequencies from the radio receiver and from the frequency standard.

Control Panel

This unit furnishes automatic and manual control for the complete equipment. It comprises relay control circuits and switching circuits, plus monitoring facilities to allow checking of the whole system. An incoming signal is selected by the selector switch on the control panel and is applied directly to input terminals of the frequency meter. The output of the frequency meter returns to the control panel, goes through relay contacts used in the range-change circuit, and then connects to the recorder amplifier and slidewire circuits.

Automatic range-adjustment is performed at the control panel in the following manner. If an incoming signal, produced either by the radiosonde transmitter or by the frequency standard, has a value of approximately 175 cycles or greater, a cam switch on the recorder closes, activating a relay in the control panel. This relay initiates operation of one of two timers. This timer operates for a period of time, determined by its initial setting, to ascertain whether the input signal is sufficiently steady over this period of time to warrant an automatic range-adjustment. If the signal does not stay present for the selected time interval, the recorder moves downscale to a temperature or humidity reading, and the timer resets.

If the reference signal is present for the required length of time (up to 30 seconds) the output of the frequency meter is continued in its connection to one side of the recorder amplifier, but the slidewire contact is disconnected from the recorder amplifier, and a point representing exactly 95 per cent of the printed chart-width (that is, nominal 190 cycles) is connected to the other side of the recorder amplifier input circuit. Thus, the recorder amplifier compares these two input voltages. At the same time the output of the recorder amplifier is disconnected from the recorder balancing motor and is connected to an auxiliary balancing motor which drives a multiturn rheostat (Helipot or Micropot). This multiturn rheostat, the range-adjustment control, is in series with the slidewire voltage-supply. As its value is changed, it changes the total slidewire voltage and the voltage of the 95 per cent tap point proportionately. The motor driving the multiturn rheostat moves in the direction to reduce to zero the difference between the 95 per cent tap point (referred to usually as the reference point) and the output of the frequency meter, derived from the steady input reference signal. This action occurs in a period of approximately three seconds, determined by electronic delay circuits on the control panel.

At the end of this time, the recorder amplifier and recorder balancing motor are returned to their normal connections to the circuit, so that the input signal is recorded normally, now at exactly 95 per cent of chart-width. Since the slidewire is a linear device, the value of all other incoming d-c signals derived from the frequency meter will be changed in the same proportion. Actually this constitutes a range adjustment of the recorder to offset any changes or drifts which are not desired in the incoming signal.

Since the final record is produced on a strip of paper, it is desirable that the 95 per cent tap point of the slidewire and the 95 per cent point on the chart correspond at all times. Accordingly, the reference or 95 per cent point is adjustable over a range of approximately ±1 per cent to compensate for expansion or contraction of the paper which may occur with changes in humidity. The zero end of the paper is fixed by the sprocket pins. The setting of this reference point adjustment determines to what point the recorder will adjust incoming reference signals, during the automatic range-adjustment cycle.

To avoid repeated recycling of the automatic-range-adjust circuit, a second timer is provided. This timer, known as the "drop-out" timer, with a range of 60 seconds, operates as follows. If after return to normal recording following the automatic range-adjustment, the signal departs from the reference frequency (that is, frequency of 175 cycles or greater) other relay circuits operate to cause the recorder amplifier to switch from the frequency meter output to the 95 per cent reference point. The recorder then records 95 per cent of scale independent of the input signal. This condition continues until the drop-out timer has completed its operating cycle. If, at the completion of this cycle, the reference signal is still absent, that is, if a humidity or temperature signal is present, the recorder moves downscale and records this signal, which is below 175 cycles. As the recorder moves below 175 cycles, it releases all the relay circuits which have operated, so that they are ready for the next reference signal which may be received.

However, if the reference signal had returned during the time interval determined by the drop-out timer, so that it is present at the completion of the timer cycle, the timer resets, the recorder returns to recording the output of the frequency meter (190 cycles), and the drop-out timer "protection" is ready to repeat the operation noted before. This cycle can be repeated as many times as the reference signal drops out until such time as the reference signal drops out, and stays out, for a period of time longer than that determined by the drop-out timer.

Figure 7 is a sample chart record showing the record produced by the range-change operation. A signal which should read 80 cycles (40 per cent of full scale) on the chart, is shown initially with an error. The same proportional error exists in the corresponding 190-cycle position. The 30-second timer causes the recorder to observe this signal for 20 seconds prior to correcting the error.

After the automatic range-adjustment, return to normal recording of the 190-cycle signal occurs, for a period of 35 to 40 seconds. Then 80 cycles is reconnected to the input circuit. This produces a short downscale motion of the recorder, operating the drop-out timer control cam, and returning the recorder to the 95 per cent reference point for the 35-second setting of the 60-second timer, before allowing recognition and recording of the 80-cycle signal, which is still present at the end of the drop-out-timer period. The 80-cycle signal now records correctly.

The reason for the incoming time delay and the drop-out timer, is that under certain conditions the airborne commutating switch which selects humidity, temperature, and reference contacts may not make positive contact immediately. This may lead to very short reference signal indications which should be ignored by the recorder. The operator, by listening to the monitor speaker, can obtain information leading to proper setting of the timers to prevent this occurrence.

Since the reference signals are produced by a commutating switch operated by an aneroid cell, the number of times that a reference signal appears is an indication of the altitude attained by the balloon. An electrically-operated counter controlled by the relay circuits which operate the automatic range-adjustment circuit, counts the number of times frequencies above 175 cycles are received. The counter is prevented from making false counts by the same timers that prevent recycling of the automatic-range-adjustment feature.

Automatic Calibration

Automatic calibration utilizes signals derived from the frequency standard. If it is desired to have the frequency standard stepped from one frequency to the next, the automatic calibration switch on the control panel is depressed momentarily. The 60-second drop-out timer used previously for protection in the automatic-range-adjustment circuit is not needed for this feature, when the frequency standard is used as a signal source. Therefore, this timer is transferred to the automatic calibration circuit to determine the length of time that a given frequency is produced by the frequency standard. At the end of each time cycle of the 60-second timer, it causes the stepper switch on the frequency standard to move one step, so that a step record, first downscale and then upscale and then downscale again, is produced. Each time the stepper switch selects the 190-cycle point, an automatic range-adjustment occurs if the range-circuit switch is placed in the "automatic" position. However, if this is undesirable, the automatic range-adjustment feature may be disconnected by placing the switch in the "manual" position.

In addition, specific frequencies may be selected from the frequency standard by stepping the stepper switch with an auxiliary control switch on the control panel.

Other Features

Other check features also are provided on the control panel including means for short-circuiting the input circuit of the frequency meter to see if the output-stage voltage is actually zero when no input frequency is present. An output-short-circuit switch also is provided to short-circuit the output stage of the frequency meter. By comparing the input and the output short-circuit conditions, the condition of the output stage is determined. If there is no shift in zero position of the pen when input and output short-circuit conditions are compared, it may be assumed that the output tube is in good condition and that the output stage is operating properly. Variations of zero under these conditions usually indicate a faulty tube having heater-cathode leakage which may cause an error in the output d-c voltage.

Mechanical Features

All units slide into the rack and plug in. Units are removable and in most cases are self-powered so that they may be serviced on the bench without the necessity for interconnection to the rack. The bails on the chassis serve to guide the connectors into place when the units are slid into the rack, and as carrying handles and chassis jacks for service. Figure 5 shows the

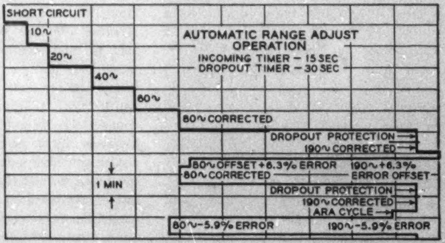

Figure 7. Sample chart record, showing two different automatic-range-adjustment cycles and portion of linearity check

Figure 8. Delay line construction

Partially assembled line (above), completely assembled and sealed line (below)

frequency-meter chassis removed from the rack for service.

Service is further facilitated by mounting the chassis in the vertical plane so that the usual bottom of the chassis opens at the front of the recorder rack and the tubes project horizontally from the back of the chassis. The front panels, which are held by separate screws, may be removed, but the chassis will stay in the rack, held by their own screws concealed under the panels. This allows accessibility to all circuits and tubes while the units are in the rack in operating condition.

A greater mechanical problem is involved in the design of the control panel assembly because it comprises not only 14 relays and circuits with associated tube controls, but also the indicating instruments, timers, input switch, control switches, counter, auxiliary balancing motor, and multiturn rheostat, audio circuits, and so forth. Therefore, the control panel is built in two parts. When it is pulled out of the rack and unplugs its connections, it may be set on the bench. Then the back panel of the control unit itself may be hinged down to allow accessibility to the inside of the control panel and to relay and tube-socket wiring and components, as shown in Figure 6. The relays are plug-in units utilizing 12-contact tube-bases and dust covers. They may be removed for replacement or service. The dust covers may be removed and the relays placed back in their sockets in case contact operation is to be observed.

Limit-of-Error

The limit-of-error of the system is determined by two factors. First, the linearity of the slidewire is extremely important. However, linear, accurate slidewires have been made for a number of years. Second, the a-c to d-c conversion linearity of the frequency meter must be well within the limits of the complete system, since all input signals are converted to direct current by this unit.

Extraneous pick-up in both the d-c and a-c circuits must be reduced to a value which will not affect the over-all limit-of-error. This is one of the major problems in a recorder of this type since there are so many different paths followed by the a-c and d-c circuits through the relays, and through the control-panel and rack cabling. Careful attention to magnetic loops in the circuits, and proper shielding, are essential. Appropriate relay contact materials must be used so that contact potentials and thermal potentials do not introduce errors in the d-c circuits. The complete recorder has a limit-of-error of ±0.25 per cent, or better, including operation of the automatic-range-adjustment circuit.

Graphical Method for Estimating the Performance of Distance Relays During Faults and Power Swings

A. R. VAN C. WARRINGTON
MEMBER AIEE

THE impedance of a transmission line of a given conductor size and spacing is proportional to its length. This fact makes it possible to build distance relays which can determine the distance to a short circuit by comparing the current in the conductors with the potential between them, since the ratio V/I is the impedance which is proportional to the distance to the short circuit.

In order to measure correctly the distance to a fault between two phases of a 3-phase line, a relay must be provided which compares the voltage between those phases and the vector difference of the currents in them. Two more identical relays, similarly connected, are required to measure the distance to faults between the other phases of the line. Similarly for ground faults, three distance relays are required; each one compares the potential between a conductor and ground with the currents in the conductor and the ground.

With distance relays connected in this manner a fault involving the phase or phases associated with the relay will cause it to measure the true impedance of the line between the relay and the fault. However, since the other two relays are energized by the currents in these phases and the voltages across the other phases, this same fault will cause them to measure values other than the true impedance, the necessary determination of which involves rather complicated and tedious calculation. Similarly, power swings which result in large angles between voltages at the ends of the system may produce current-voltage relations which cause distance relays to measure impedances even more tedious to evaluate by mathematical computation. Finally the slow clearing of a fault may cause a power swing, so that there will be a combination of swing and fault conditions to analyze.

The purpose of this paper is to describe a method of determining quickly what impedances all phase and ground distance relays measure during all of these fault and swing conditions. The method is generally relatively simple, employing only a ruler and a protractor or a draftsman's 30- 60- 90-degree triangle, and requiring knowledge only of the positive and zero sequence impedances of the system.

The validity of the graphical method used is established in the section on Derivation of Construction for charts, where the calculations are summarized in the form of tables with all values given in terms of the phase sequence impedances of the system. The expressions in the tables and the vector algebra used in calculating them have been made as easy to read as possible by limiting the use of subscripts to one reference at a time and choosing them to be self-evident, so that constant reference to the nomenclature list is not necessary.

It was observed that there was a certain symmetry in the expressions for the impedances seen by the relays under different fault conditions and this indicated that relatively simple charts could be used to reduce the work of calculation and that relay performance would be predicted by drawing the relay characteristic on the same chart.

The protected section was assumed to be a single line. Parallel lines were not considered because they do not appreciably affect the results for faults near the ends of the protected section. These are the only faults that need be considered since this analysis is concerned only with the possibility of relays' tripping on faults beyond the end of the protected section.

Fault Charts

These charts show, as vectors on an impedance diagram, the relationship between the impedance seen by the relay in the faulted phase or phases and the impedances seen by the relays in the other phases. Line-to-line, line-to-ground, and double-ground faults are considered for phase relays and for ground relays. Three-phase faults were not considered because they are symmetrical so that all the relays are presented with the same impedance.

CONSTRUCTION OF TYPICAL CHART

When supplied with the proper currents and potentials, the relay associated with the faulted conductor or conductors measures the positive sequence impedance of the line between the relay and the fault, including any arc or contact resistance in the fault. The impedance and arc resistance measured by the relays in the phases not directly associated with the fault, differs from the true impedance by an amount which depends on the type of fault and which can be obtained graphically as shown in subsequent paragraphs.

Phase Relays with Line-to-Line Faults, Figures 1 (A), (B), and (C)

Figure 1(A) is an impedance diagram with resistance and reactance co-ordinates R and X. The line AB is a vector representing the true (positive sequence) impedance of the protected transmission line whereon F is the fault location. The lines AS and BL represent the total system impedance behind the relay and

Paper 49-154, recommended by the AIEE Relays Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer General Meeting, Swampscott, Mass., June 20–24, 1949. Manuscript submitted March 22, 1949; made available for printing April 28, 1949.

A. R. VAN C. WARRINGTON is with the General Electric Company, Philadelphia, Pa.

beyond the protected line respectively and can be calculated easily from a knowledge of the short-circuit currents at the line terminals *A* and *B*, deducting the current that flows through the line.

The impedance measured by the relay in the faulted phases *2-3* (neglecting arc resistance) is represented by the line *AF* which is the phase-to-neutral or positive-sequence impedance of the line between the relay and the fault, and is referred to as the true impedance. The phase *3-1* relay sees an impedance which is leading the true impedance, and the phase *1-2* relay a lagging impedance, which are obtained as follows: Join *SF* and draw lines from *S*, 60 degrees on each side of *SF*, to meet perpendiculars to *SF* drawn from *F* at *M* and *N*. *AM* is the impedance seen by the *3-1* relay and *AN* the impedance seen by the *1-2* relay.

In Figure 1(B), and all the ensuing diagrams, arc resistance is considered but, for the sake of simplicity in the explanation, all the impedances of the system are considered to be of the same phase angle, that is, the system is homogeneous and points *S*, *A*, *B*, and *L* are on the same straight line. As shown in the previous paragraph and in Figure 1(A), if the phase angle is not uniform throughout the system, it is necessary only to draw the extra line *SF*.

SM is drawn at 60 degrees leading *SF*, as in Figure 1(A), but the arc resistance R_F/C is added at 60 degrees leading the *R* axis so that the total impedance Z_{31}' seen by the phase *3-1* relay is the vector AF_{31}. Z_{12}' is found in a similar manner, but using a 60 degree lagging shift. By drawing the perpendiculars from *A* instead of *F* the points M_A and N_A can be found which give the impedances for a fault at the relay location *A*. The addition of the arc resistance locates the points A_{31} and A_{12} so that now four points have been located which define the fault areas; these areas are shaded in Figure 10 to show their relationship to typical relay tripping areas, which will be discussed later.

The arc resistance is expressed as R_F/C instead of R_F because only the fraction *C* of the fault current flows through the relay; the rest comes from the line section on the other side of the arc.

Ground Relays with Line-to-Line Fault, Figures 2 (A) and (B)

The procedure for Figures 2(A) and (B) is much the same as used in Figures 1(B) and (C). The diagrams are similar except for the facts that the angle which *SM* and *SN* subtend from *SF* is 30 degrees this time, and that the arc resistance is less by the ratio $\sqrt{3}$ and is drawn at 30 degrees from the *R* axis. These ratios and angles are summarized for the various faults in Table V. Z_1', the impedance presented to the phase *1* relay, is infinite and therefore not shown on Figures 2(A) and (B).

Phase Relays with a Line-to-Ground Fault, Figures 3 (A) and (B)

Figure 3(A) shows the impedance produced by a ground fault as viewed by the phase relays. The lines *SM* and *SN* are drawn at 30 degrees on each side of *SF* as in Figure 2(A) but they are now extended to *T* and *W* by the zero sequence component $Z_0/C\sqrt{3}$ because the ground circuit is involved. The arc resistance is then added as it appears to the relay. $\sqrt{3}R_F/C$, at 30 degrees from the *R* axis see Table V. Z_{23}' is not shown because it is infinite.

Ground Relays with a Line-to-Ground Fault, Figures 4 (A) and (B)

In this case the relay current is a mixture of phase and residual current and the value *C* is replaced by a hybrid value which we will call *C'* and which is $C-C_0 Z_0'/Zp'$. This means that *SM* and *SN* are no longer at 30 degrees or 60 degrees from *SP* but the angle depends on the relative values of *C* and C_0. The construction is therefore a little less convenient than before and is as follows: Draw a line *MN* through *F* at right angles to *SF* so that $FM=FN=\sqrt{3}Z_n/C'$. Draw $MT=\sqrt{3}Z_0/C'$ leading *SF* by 30 degrees and draw $NW=\sqrt{3}Z_0/C'$ lagging *SF* by 30 degrees. Finally draw the arc

resistance component $\sqrt{3}R_F/C'$ at *T*, leading the *R* axis by 30 degrees and draw $\sqrt{3}R_F/C'$ at *W*, lagging the *R* axis by 30 degrees.

It will be noted that this chart was drawn to a smaller scale because the quantity $\sqrt{3}R_F/C'$ is too large for the same scale to be used.

Phase Relays with a Double-Ground Fault, Figure 5

One phase relay measures the true impedance to the fault, and that is the one associated with the two phases involved in the double-ground fault. The expressions for the impedances measured by the other two relays are too complicated to show graphically, but it is safe to assume that, since the zero sequence components of the current and potential tend to cancel out, due to the delta connections of the relay, the impedance measured by the relays will be similar to that for a line-to-line fault, Figure 1(B). This assumption will be verified later when the mathematical analysis is given. In Figure 5, a typical case has been worked out and it will be seen that Z_{31}' and Z_{12}' are practically the same as in Figure 1(B), taking into account the change in scale.

Ground Relays with a Double-Ground Fault, Figures 6(A) and (B)

Here again the impedance measured by the relays in the two unfaulted phases is too complex to show graphically, but it will be shown later that in one phase the relay measures a reactance equal to or greater than the true reactance to the fault, while the relay in the other phase measures reactance equal to or less than the true value. Reactance is mentioned because impedance and mho relays are seldom used for ground faults on account of their vulnerability to fault resistance, which may be high in ground faults. In the meantime, Figure 6(A) was calculated for a wide range of conditions and shows how the measured impedances compare with the true impedance *AF*. Figure 6(B) shows the fault areas of impedance seen by the relays under the same range of conditions for faults over the whole section.

Reference to the vector diagrams, Figures 6(C) and 6(D), will show why one relay measures too much reactance and the other too little. In Figure 6(C), which represents the general case where *C* and C_0 are comparable in magnitude, the relay potential V_2' is seen to be almost in phase with the current I_2' so that the reactance measured by the phase 2 relay

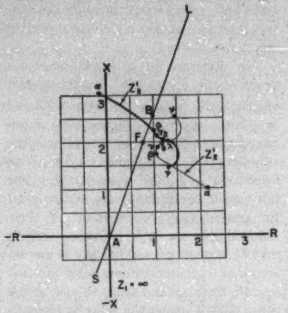

Figure 6(A). Impedances seen by ground relays with a double-ground fault at *F*

is small and the relay will overreach; the relay potential V_3' however is leading its current I_3' by a considerable angle so that its measured reactance is large and the relay will underreach. The true impedance would be roughly half the potential V_{23}' divided by one of the $I\phi'$ components. $I\phi'$ is the current that would flow between conductors if the ground were not involved.

Figure 6(D) represents the case where there is a grounded neutral transformer nearby, but little generation, so that C is small compared with C_0. In this case it can be seen that the phase *2* relay will measure the same as or greater reactance than the phase *3* relay.

DERIVATION OF PARAMETERS AND CONSTANTS

Z_0 can be obtained from the system impedance diagram. R_F can be estimated or can be calculated as explained in a previous paper.[1] C and C_0 can be either 0 or 1 on a radial system but, on the average system with many connections and parallel paths, they usually would be between 0.3 and 0.7. C also can have an angular component, for example, where there is double-end feed with a phase displacement between the generators at the two ends, the angular component of C would be leading on one side of the fault and lagging on the other, the sum of these two angles being equal to the angle between the sources of generation. For example, if there were 25 degrees between the generated electromotive force at *S* and the generated electromotive force at *L*, the angular component of C might be 12 degrees at *A* and 13 degrees at *B*, which can be neglected in most cases. The angular component of C_0 would be negligible, because the only source of zero sequence potential is the fault.

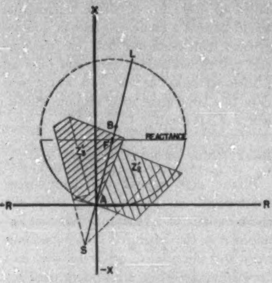

Figure 6(B). Ground relay characteristics on a double-ground fault diagram

$Z_1 = \infty$

In most cases the relays in the other phases will not operate for external faults by a considerable margin, so that the phase angle of C can be ignored. In a borderline case it would be advisable to recalculate, taking into account the angle of C. In the case of the ground relay with single-phase ground faults the value of $C - C_0\, Z_0'/Z_p'$ is usually small so that the impedance seen by the ground relays in the other phases is very large and need not be calculated since the relays will not operate.

SUPERPOSITION OF RELAY CHARACTERISTICS

The purpose of making these impedance charts is, of course, to find out how the relays respond when a fault occurs. This can be done quite accurately by drawing the relay characteristic on the diagram, using the same ohmic scale. Relays that have accurate and consistent characteristics will of course be easier to handle. In other words, if the relay has a perfectly circular characteristic which remains the same over a wide range of current or potential, the behavior of the relay can be ascertained at once by taking a pair of compasses and drawing the circle. If the relay characteristic is not circular, or if it varies, it will be necessary to draw a family of curves.

The relay characteristics shown superimposed on some of the diagrams are those of typical distance relays for long and short lines. The long line relay is a mho relay whose characteristic circle is the small one shown between the origin *A* (relay location) and the fault *F* as explained in previous papers.[1,2] The small characteristic of the mho relay is best for long lines because it is less liable to trip on power swings. It will be shown later that this smallness also is desirable on any line because, the smaller the characteristic, the more effectively the relay is confined to tripping only on faults within the zone, and phase with which it is associated.

The short-line characteristic is that of the reactance relay which was described in a previous paper.[3] The reactance relay is prevented from tripping on faults behind the bus by a directional starting unit which is also a mho unit, so that the tripping area is the area enclosed between the reactance characteristic and the larger mho circle. Earlier reactance relays

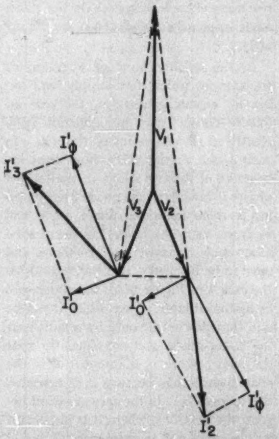

Figure 6(C). Vector diagram of double-ground fault average case

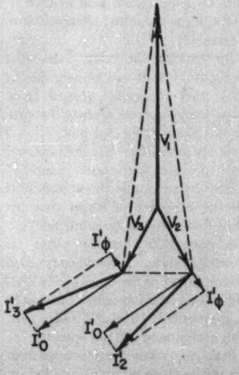

Figure 6(D). Vector diagram of double-ground fault at relay near grounding transformer (whose directional or starting units were polarized by potential from another phase pair) had an angle and diameter depending on the type of fault and the angle of the polarizing potential; for such relays the starting unit circle would have to be drawn in different positions depending on the phases with which the relays were associated.

FAULT AREAS

The arc resistance is a function of the fault current and the conductor spacing.[1] It is shown as a constant value in the diagrams for the sake of simplicity. In practice it will be less at the line terminal which has the heavier short-circuit current.

In Figure 1(B) the point M indicates the impedance measured by the relay in phase pair *3-1* for a phase *2*-phase *3* fault at F, while the point M_A indicates the impedance measured for a fault at A with solid faults in both cases. Similarly N and N_A are corresponding values measured by the phase *1-2* relay. The points F_{31}, A_{31}, F_{12}, and A_{12} are corresponding values for arcing faults.

BEHAVIOR OF PHASE RELAYS

Figure 1(C) shows the characteristics of typical distance relays superimposed on Figure 1(B). The directional starting unit which limits the characteristics of the reactance unit also is a mho unit and it is apparent that neither the reactance relay nor the mho relay can operate for faults in other phase pairs with this particular system arrangement. On the other hand, if the generator S were closer to the relay A, the points M_A and N_A would be closer to A and the phase *3-1* relay might operate. It is quite clear that neither of the relays in the unfaulted phase pairs would overreach.

By drawing the relay characteristics on Figure 3(A) it can be seen, in Figure 3(B), that a nearby ground fault in phase 1 may operate a phase distance relay in phase pairs *1-2* and *3-1*. This gives the advantage that the phase relays may provide high-speed tripping on nearby ground faults which would otherwise be tripped in a longer time by inverse time residual (ground) relays; the disadvantage is that the phase target showing at station A would contradict the ground target at the other end of the line and cause confusion unless this condition is appreciated. The *2-3* relay gets no fault current and will not operate.

Hitherto, when targets appeared on two of the phase relays at one end of the line and only one at the other, it was often assumed that one of the targets had failed to operate. A better explanation might be that a phase-to-phase or double-ground fault occurred and that the correct relays worked at each end plus an additional relay at the end which was close to a large generating station, that is, where AS is small.

BEHAVIOR OF GROUND RELAYS

Figure 2(B) shows the fault areas constructed in Figure 2(A) with the characteristic of a reactance relay superimposed on the diagram. The impedance relay and the mho relay circles were not drawn because they are seldom used for ground faults on account of the probability of appreciable resistance in ground faults. It can be seen that two ground reactance relays may operate on phase-to-phase faults, overreaching in the leading relay and underreaching in the lagging relay. Figures 6(B) and (C) show the same tendency in double-ground faults. It is for this reason that it has been customary to provide a blocking relay with ground distance relays which prevents them from tripping when the fault involves more than one phase. On the other hand, if the blocking relay were arranged to block only the ground relay that overreached, the other relay would operate correctly though it would not reach as far as its ohmic setting would indicate. This would increase the value of ground distance relays since they could back up the phase relays and, in some cases, could be used for all faults, their reach on phase faults being better on lines with a high ratio of X to R because the reactance error decreases as the line phase angle approaches 90 degrees, see Figure 6(A).

In the neighborhood of a grounding transformer which may supply load but has no nearby generation, the zero sequence current may preponderate sufficiently so that C_0 is many times C. In such a case Figure 6(D) shows that the behavior of the two relays in the faulted phases is reversed; the phase *2* relay now has a more favorable phase angle and measures more reactance, but the phase *3* relay may measure less reactance and have to be blocked. This corresponds to the case 4 in Figure 6(A) and which will be discussed later. Meanwhile, it can be said that this is true only for a fault near the transformer, and consequently near the relay, where it is immaterial if the relay overreaches because it is expected to trip anyway. In the case of a fault beyond the next bus, where it is important for the relay not to overreach, C_0 would be less and the phase *3* would be more likely to underreach. In intermediate cases both relays would measure the correct reactance so that it would not matter which was blocked.

The diagram for a single phase-to-ground fault, Figure 4(A), was drawn to a smaller scale because the term $\sqrt{3}Z_0/C'$ is a large quantity. Figure 4(B) shows the characteristic of a reactance relay superimposed on Figure 4(A). The impedance and mho characteristics are not shown because they are seldom used for ground faults on account of their vulnerability to fault resistance which may be high in ground faults. It can be seen that a ground distance relay will not operate for a ground fault on one of the other phases unless the relay is close to the bus of a large station so that Z_N and Z_0 would be small causing the fault area to be closer the relay at A. In other words, there is no chance of overreach on single-phase ground faults in other phases and practically no chance of having more than one target show.

OTHER RELAY CHARACTERISTICS

In the foregoing only distance relays with standard connections have been considered, but it is possible to superimpose the characteristics of any other type of relay. It must be remembered, however, that distance relays polarized by potential other than the one used for the restraint windings have a family of circles for different fault conditions and hence their characteristics are more difficult to show on an impedance diagram. Distance relays using current from only one phase require the calculation of a new table of impedances, since those given in this paper are based on the difference between two phase currents for the phase relays and the difference between the phase and ground currents for the ground relays which are necessary for accurate distance measurement.

The behavior of relays other than distance relays also can be analyzed. For instance, the pick-up of a residual power relay (V_0I_0) can be determined by reading off the values of V_0 and I_0 in Table I. Similarly the operation of a phase selector using $V_0 \times I_n$ or $V\delta \times I_0$ can be determined in its application to single-pole switching under different fault conditions. There also are polyphase directional relays, with and without voltage restraint, whose behavior can be predicted by this method.

Power Swing Charts

On a system where faults are cleared by high-speed (1 cycle) relays and fast circuit breakers (8 cycle or less) the effects of power swings can be considered alone because we can generally assume that the fault will be cleared before the system swings apart appreciably. On the other hand where low-speed (induction disk) relays are used, or a mixture of high-speed and slow relays are used, the swing may be appreciably under way before the fault is cleared and there may be a period where the swing and the fault are present simultaneously.

First the case of the power swing alone will be considered, and then the case of a power swing with a fault. The graphical method employed can be used, not only to check the relay operation in the different phases, but also to determine the maximum load that can be transmitted over a line without causing relay operation. It is also a guide to the selection of suitable types of phase relays.

In analyzing the effects of power swings on relays many of the variables which complicate system stability computations can be neglected, because they have

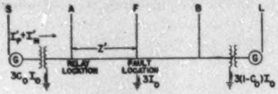

Figure 7. Simplified impedance diagram of a transmission system

negligible effect on the part of the power swing locus in the region of the relay characteristic.

The effect of these variables is to bend the extremities of the power swing locus up or down into a large circle, which goes through or near the electrical center of the system and some point on the X or $-X$ axis, but the portion of the locus which is within the relay tripping characteristic is not changed enough to affect the chance of tripping appreciably. On the other hand, the simplification of the diagram is very much worthwhile.

THE POWER SWING WITHOUT A FAULT

Figure 7 shows the electric circuit representing the system when all the generation beyond the two ends of the protected line are lumped to represent an equivalent machine at each end. Figure 8 shows the generated electromotive forces, E_S and E_L, at the two ends of the system and their difference voltage SL which exists across the system and causes the transfer current I_S to flow through it. This transfer current flows through the whole system so that, by dividing it into the voltages, an impedance diagram results, Figure 9.

The origin of the diagram is drawn at the relay location A so that the impedance will appear as measured from the location A. The relay at A, for instance, would measure an impedance value AB for a fault at B, but, in the case of power swing with angle θ_S between the generated voltages, it would measure the impedance AO. As the swing became more severe and the angle of separation increased to θ_S' the impedance measured by the relay would decrease to the value AQ' which might be within the tripping characteristic of the relay. Similarly, if the origin of the R and X axes had been drawn at B, a line drawn from B to any point would be a vector representing the impedance seen by a relay at B for a condition represented by that point.

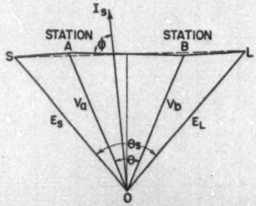

Figure 8. Simplified voltage diagram of a transmission system

Assuming equal generated electromotive forces, the power-swing locus will be the locus of the apexes of a series of isosceles triangles with a common base SL, so that the locus must be a straight line bisecting SL at right angles.

A practical example of the use of this method is to find approximately how far apart the system can swing without causing the relays to trip. Referring to Figure 10, AB is the impedance of the protected section, SA is the system impedance behind terminal A, and BL is the system impedance beyond terminal B. Draw a line perpendicular to SL through its midpoint. From the point O where this line cuts the relay characteristic, draw lines to L, S, A, and B. LOS is the smallest angle θ_S between the generated electromotive forces at L and S at which the relay at terminal A will trip. BOA is the smallest angle θ between the terminal voltages at A and B at which the relay at A will trip, and AO is the impedance it sees.

The power-swing locus shown in Figure 10 is for equal generated electromotive forces and no line capacitance. These assumptions simplify the construction and have negligible effect on the angles θ and θ_S at which the relay operates.

Where only high-speed relays are concerned, the fault will be cleared promptly before a power swing can progress very far but, while the circuit breaker is open, the system may continue to swing apart and may oscillate about a new position when the circuit breaker is reclosed. Consequently the behavior of the relays may be checked first with a fault chart such as described in the section on Fault Charts and then with the power swing diagram.

On the other hand, on systems where both fast and slow relays are used in different line sections, a fault may not be cleared promptly if it occurs in a section having a slow relay. While the slow relay is operating, the high-speed distance relays are subjected to a mixture of fault and swing conditions which are dealt with below.

POWER SWING ON A FAULTED LINE

In the following discussion only a phase-to-phase fault will be considered for the following reasons: in 3-phase faults the flow of power is completely interrupted by the fault and the three relays can see only the fault until it is cleared leaving only the power swing. Double-ground faults with a power swing involve a very complicated calculation and their effect on the ohmic reach of distance relays is sufficiently similar to the effect of a phase-to-phase fault to accept the results of the latter. A single-phase fault was not considered because it is not likely to produce a power swing sufficiently severe to cause relay operation unless the system is loaded close to its steady-state limit of stability.

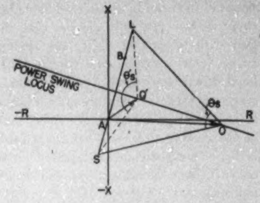

Figure 9. Simplified impedance diagram of a power swing

The effect of a phase *2* to phase *3* fault on Figure 10 is to change the length of the impedance vector SL representing the total system impedance and to shift it in the leading direction in phase *3-1*, and an equal amount in the lagging direction in phase *1-2*. SL is now multiplied by $2/\sqrt{3+(SL/SF)^2}$ and shifted through an angle ϕ_K-30 degrees where $\phi_K=\tan^{-1}SL/\sqrt{3}SF$. Figures 11 and 12 illustrate this change. It should be noted that, in Figure 11, the angle $S'O'L'$ is not the angle θ_S between the generated electromotive forces, but $\theta_s+\phi_K$, so that θ_S is $S'O'L'-\phi_K$. A similar consideration holds for Figure 12 except that $\theta_S=S'O'L'+\phi_K$.

The presence of the fault also tends to bend the power swing locus upwards so

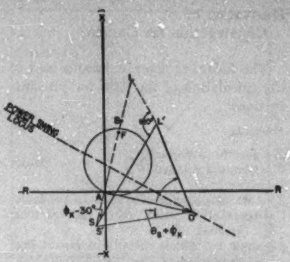

Figure 11. Simplified diagram for impedance seen by phase 1-2 relay during a phase 2-phase 3 fault with a power swing

that it will form a circle above the straight locus representing the power swing without the fault. The error in the impedance measured by the relay caused by assuming the power swing locus still to be a straight line is greater than the error caused by this assumption when no fault is present but, since the error will be substantially tangential to the relay characteristics where they meet the power swing locus earliest, it can again be accepted without much risk of a wrong prediction of relay performance. In borderline cases, or cases where E_S is greater than E_L, the relays can be checked more precisely by using the charts which are provided in Miss Edith Clarke's paper.[4]

The procedure for checking the relays, as before, is merely to draw the impedance characteristics of the relay upon the power swing diagram, using the same ohmic scale, as in Figures 10, 11, and 12. The impedance and reactance relay circles were not shown because such relays are not suitable for heavily loaded lines which are long enough to be liable to trip on power swings.

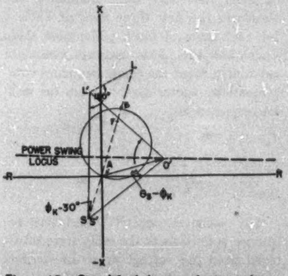

Figure 12. Simplified diagram for impedance seen by phase 3-1 relay during a phase 2-phase 3 fault with a power swing

Derivation of Construction for Charts

The following nomenclature is used in the calculation of the data for the illustrations:

Symbols

E = generated voltage
V = terminal voltage
I = current
Z = total impedance of system to the fault
C = distribution ratio, relay current/total current
ϕ = angle by which current in circuit lags potential
θ_S = angle between generated electromotive forces
θ = angle between two station voltages
a = operator equivalent to $1\underline{|120}$ degrees
j = operator equivalent to $1\overline{|90}$ degrees
R_F = fault resistance
R_G = resistance in ground return
S = leading or sending end of system
L = lagging or receiving end of system
A and B = stations where relays may be located
F = fault location

Other Subscripts

12, 23, 31 = refer to the three pairs of phases
p = positive sequence
n = negative sequence
0 = zero sequence

Primes

A single primed quantity pertains to the section protected by the relay.
Z' = impedance of protected section or as seen by a relay in the protected section
V' = voltage at relay terminal
I' = current measured by the relay

Figure 7 shows the equivalent impedance diagram of a transmission system. Figure 13 shows the positive, negative, and zero sequence impedance networks corresponding to Figure 7 for different types of faults. By a simple mathematical procedure, such as the use of Kirchoff's law, the currents in these networks can be calculated. The relay currents (which flow in the left-hand half of each network) thus calculated are shown in the first three lines of Table I for each type of fault. The next three lines show the phase currents which are calculated from the phase sequence components by vector algebra from the well-known relations

$$I_1 = I_p + I_n + I_0$$

$$I_2 = a^2 I_p + a I_n + I_0$$

$$I_3 = a I_p + a^2 I_m + I_0$$

The positive, negative, and zero sequence potentials at the relay were calculated from the voltage drops in the networks (which are shown in Figures 14, 15, 16, and 17) and the phase potentials were calculated from the phase sequence

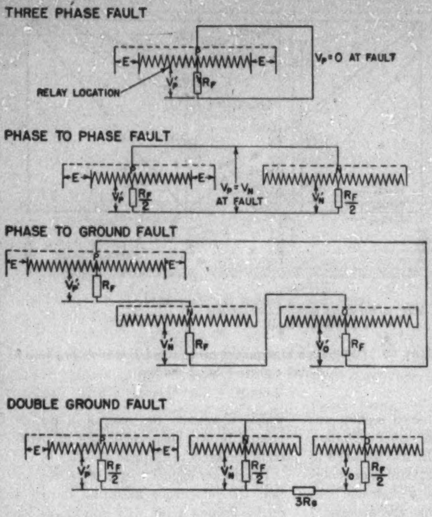

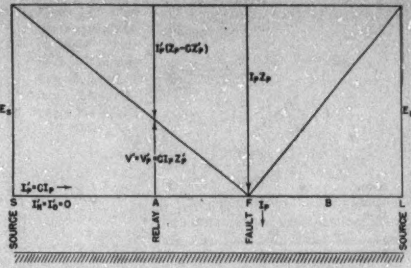

Figure 13 (left). Sequence networks on a transmission system

Figure 14 (above). Distribution of phase sequence currents and potentials (during a balanced 3-phase fault)

potentials by equations corresponding to the above. The phase potentials were then combined to give the line-to-line potentials in the last three lines of Table I. All these quantities have the same denominator for a given type of fault so, in order to simplify the tables, all quantities are multiplied by the denominator, *K*, for the particular fault.

In Table II these quantities were combined in the manner in which they are supplied to phase distance relays, and the impedances measured by the relays were calculated. Z_{12}', Z_{23}', and Z_{31}' are the impedances measured by the phase relays and Z_1', Z_2', and Z_3' are the impedances measured by the ground relays. Phase relays receive delta currents and potentials so that

$$Z_{12}' = \frac{V_{12}'}{I_1' - I_2'};\; Z_{23}' = \frac{V_{23}'}{I_2' - I_3'} \text{ and } Z_{31}' = \frac{V_{31}'}{I_3' - I_1'}$$

where the primed values refer to the protected section. Ground distance relays receive Y-potentials and a combination of phase and residual current (I_{res}), so that

$$Z_1' = \frac{V_1'}{I_1' + \dfrac{Z_0' - Z_n'}{3Z_p'} I_{res}'} = \frac{V_1'}{I_1' + \dfrac{Z_0' - Z_p'}{Z_p'} I_0'}$$

Similar expressions for Z_2' and Z_3' are shown in Table III.

The impedances measured by the relays are thus expressed in terms of the total system impedances Z_p, Z_n, and Z_0 and the arc resistance R_F. In the double-ground faults the term R_G is used to denote the resistance of the ground return path.

In Tables I, II, and III, the operator "a" was used for convenience in calculation. In constructing vector diagrams, however, it is easier to use a single operator having amplitude and angle such as $\sqrt{3}\,\overline{|90^\circ}$ rather than the corresponding function $(a^2 - a)$.

Inspection of Tables II and III will show that all the relays measure the true impedance Z_p' plus some additional terms. Table IV lists the additional impedance. The final step is to convert this information to something that can be drawn quickly.

Let us consider the first line of Table IV. The additional impedance for the *1-2* phase relay for a phase *2*-phase *3* fault is $(\sqrt{3}/C)\ Z_n\overline{|90^\circ} + (R_F/C)\overline{|60^\circ}$. Now Z_p can be substituted for Z_n without appreciable error and Z_p/C is the line impedance *SF* because $C = I_p'/I_p = Z_p/Z_F$ where Z_F is the positive sequence impedance on the relay side of the fault.

This means that $(\sqrt{3}/C)\ Z_n\overline{|90^\circ}$ can be simplified to $\sqrt{3}\ SF\overline{|90^\circ}$ which is the line *FN* on Figure 1(B). Or, as will be seen by the application of trigonometry, it is only necessary to draw a line at 60 degrees lagging *SF* to intersect a perpendicular from *F* and thus to find the point *N* which gives the impedance Z_{12}' seen by the *1-2* relay, excluding arc resistance. Arc resistance can then be added, if necessary, as described previously.

In two of the other cases in Table IV the first expression is $Z_n\overline{|90^\circ}/C\sqrt{3}$. Similarly, it can be shown that this vector can be conveniently constructed by drawing a line at 30 degrees to *SF* to intersect the perpendicular from *F* and thus to locate the points *M* and *N*.

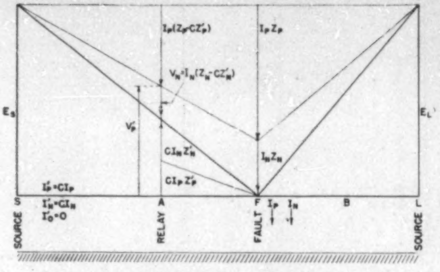
In the expression for the impedance seen by ground relays during a single-phase-to-ground fault the denominator is not *C* but *C'* which is $C - C_0Z'/_0Z_p'$.

This means that the expression $(\sqrt{3}/C')\ Z_n\overline{|90^\circ}$ has to be drawn without recourse

Table IV. Impedance Measured by Relays in Addition to True Impedance

Relay	Three Phase	Phase *2*-Phase *3*	Phase *1*-Ground
Z_{12}'	$\frac{R_F}{C}$	$\frac{1}{C}\left(\sqrt{3}Z_n\overline{\vert 90^\circ}{}^* + R_F\overline{\vert 60^\circ}\right)$	$\frac{1}{C\sqrt{3}}\left(Z_n\underline{\vert 90^\circ} + Z_0\underline{\vert 30^\circ} + 3R_F\underline{\vert 30^\circ}\right)$
Z_{23}'	$\frac{R_F}{C}$	$\frac{R_F}{2C}$	∞
Z_{31}'	$\frac{R_F}{C}$	$\frac{1}{C}\left(\sqrt{3}Z_n\underline{\vert 90^\circ} + R_F\underline{\vert 60^\circ}\right)$	$\frac{1}{C\sqrt{3}}\left(Z_n\overline{\vert 90^\circ} + Z_0\overline{\vert 30^\circ} + 3R_F\overline{\vert 30^\circ}\right)$
Z_1'	$\frac{R_F}{C}$	∞	$\frac{3}{2C'}R_F$
Z_2'	$\frac{R_F}{C}$	$\frac{1}{\sqrt{3}C}\left(Z_n\overline{\vert 90^\circ} + R_F\overline{\vert 30^\circ}\right)$	$\frac{\sqrt{3}}{C'}\left(Z_n\underline{\vert 90^\circ} + Z_0\underline{\vert 30^\circ} + \sqrt{3}R_F\underline{\vert 60^\circ}\right)$
Z_3'	$\frac{R_F}{C}$	$\frac{1}{\sqrt{3}}\left(Z_n\underline{\vert 90^\circ} + R_F\underline{\vert 30^\circ}\right)$	$\frac{\sqrt{3}}{C'}\left(Z_n\overline{\vert 90^\circ} + Z'\overline{\vert 30^\circ} + \sqrt{3}R_F\overline{\vert 60^\circ}\right)$

* $\overline{|90^\circ}$ means lagged in phase by 90 degrees, and similarly $\underline{|90^\circ}$ means advanced in phase by 90°.



$V_{23}'=\sqrt{3}(V_P-V_N)$ AND IS ZERO AT THE FAULT

Figure 16. Distribution of sequence currents and potentials in phase 1 during a phase-1 to ground fault

to the 60-degree projection line, which takes a little longer than the previous cases. Similar expressions for Z_0 and R_F also have to be worked out. Fortunately, this diagram is seldom constructed because the relays in the unfaulted phases measure such a high impedance that there is practically no chance of their operating.

PHASE RELAYS WITH DOUBLE-GROUND FAULTS

In the section on Fault Charts it was stated that the relays in one of the unfaulted phase pairs measured the correct reactance, or more, and that the other relay measured the correct reactance or less. This can be verified by working out a few cases, first of all limiting cases, such as for zero arc resistance, then a typical case with average values. For instance for a solid fault R_F and R_G will be zero and the expression for Z_{12}' in Table II will give

$$Z_{12}'=Z_p'+\frac{\sqrt{3}Z_nZ_0}{CZ_0\,\underline{|90°}+CZ_n\,\underline{|30°}}$$

Since Z_0 is usually several times Z_n, the term $Z_0\,\underline{|90°}$ will be the dominant figure in the denominator and the expression will approximate roughly to $Z_p'+\sqrt{3}Z_n\,\underline{|90°}$ which is similar to the expression for the phase 2-phase 3 fault. If R_G is infinite there will be no path through the ground and the expression will be exactly the same as for the phase 2-phase 3 fault.

A typical case was worked out using the following system parameters. The total system impedance, when simplified to a single impedance between two generating sources, was taken as 10 ohms secondary, at an angle of 70 degrees lag and the zero sequence impedance was taken as three times the positive. The impedance of the protected section was assumed to be $0.75+j2$ ohms secondary and the arc resistance R_F was assumed to be 1/2 ohm, which is 1/2 ohm in each network; C and C_0 were both made one half. Inserting these values in the expression for Z_{12}' under the column phase 2-phase 3-ground in Table II we get $Z_{12}'=Z_p'+6.7-j1.63$. Similarly for Z_{31}' we get $Z_p'-4.56+j4.38$. These values are plotted in Figure 5 and can be seen to lie close to the points corresponding to the phase 2-phase 3 fault, Figure 1(B).

GROUND RELAYS WITH A DOUBLE-GROUND FAULT

In the case of ground relays, the impedance measured is again too complex to show graphically, but an approximation can be made by considering the limiting cases. One extreme case is when the impedance of the ground circuit is infinite, so that the diagram is the same as for a phase-to-phase fault, Figure 2(B). When the arc resistance and ground resistance are zero, that is, R_F and R_G are made zero in the expressions for Z_2' and Z_3', it will be seen that the relays in phases 2 and 3 will both measure correctly for a 2-3, ground fault. Another limiting case is when Z_0 is assumed equal to Z_p and $R_G=0$, which represents the case of a perfect ground return; here again the measurement is correct in all three phases.

It appears logical therefore to assume that the impedance measured during a double-ground fault with conditions intermediate between these extreme cases would be on some locus between Figure 2(B) and the correct measurement. In order to verify this assumption, the expressions for the impedance measured by the relays were worked out for a number of typical cases, using the same system parameters as for the preceding discussion on the phase relays but varying C and C_0.

The values shown in Table V are to be multiplied by $1/D$ where D is the ohmic distance of the fault from the receiving end, L, expressed as a fraction of the total distance SL. Figure 6(A) shows the case where the fault is in the middle of the system ($D=0.5$). The points are lettered according to the cases in Table V. Figure 6(B) ignores case ψ, because it represents a special case, and shows the general areas of tripping for the phase-2 and phase-3 relays. Phase-1 relay gets negligible current and does not operate. The table shows that, for a fault between phases 2 and 3 and ground, the phase-2

Table V. Additional Impedance Measured by Ground-Distance Relays During Double-Ground Faults

Case	C	C_0	R_G	Z_2'	Z_3'	Comment
α	1	0	∞	$1.4-j\,1.01$	$-0.91+j\,1.01$	Phase-to-phase fault
β	1	0	$^1/_2$	$0.3-j\,0.27$	$0.24+j\,0.27$	Ungrounded generation behind relay
γ	1	1	$^1/_2$	$0.32-j\,0.11$	$0.31+j\,0.12$	Stub end feed
δ	$^1/_2$	1	$^1/_2$	$0.54-j\,0.04$	$0.54+j\,0.04$	Common case
λ	0.43	1	$^1/_2$	$0.58+j\,0$	$0.58-j\,0$	Both relays measure same reactance
ψ	0	1	$^1/_2$	$0.68+j\,0.53$	$0.58-j\,0.54$	Grounding transformer but no generation behind relay

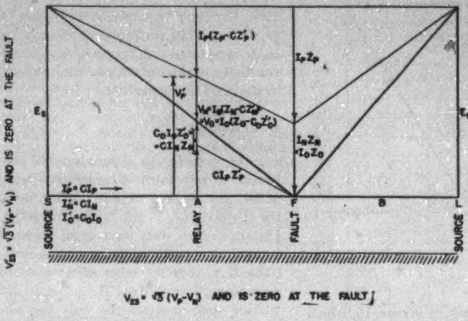

Figure 17. Distribution of phase sequence currents and potentials in phase 1 for a phase 2-phase 3 to ground fault

and phase-*3* relays would measure the correct impedance plus an additional impedance of the form $R-jX$. Ground-distance relays are usually of the reactance type so that they would ignore the additional resistance; the additional reactance is about the same for the two relays except that, if $C>0.43C_0$, it is positive for phase *3* and negative for phase *2*. If $C<0.43C_0$ the signs are reversed as in case ψ. It is seldom that $C<0.43C_0$ for a fault just beyond the end of the protected section where overreaching would be undesirable but, if such a case were encountered, it would be necessary to block phase *3* instead of phase *2* on a *2-3* ground fault.

This means that the reactance ground relay in phase *2* will overreach and the relay in phase *3* will underreach on double-ground faults in most cases, the additional impedance being zero if $C=0.43C_0$. It is the present practice with ground distance relays to block them on double-ground faults, but the foregoing reasoning shows that in most locations (where $C>0.43C_0$) the relay in the lagging one of the two faulted phases could be permitted to operate on all faults and hence greatly extend their usefulness.

POWER SWINGS

The construction of the power swing without a fault requires no further elucidation than has been given under Power Swing Charts. However, it must be repeated here that this construction is based on equal generated voltages at each end of the system and with no shunt loads or capacitances. These assumptions are permissible because the change in the power swing locus caused by allowing for shunt impedance and unequal voltages is substantially tangential to the relay characteristics where they intersect the power swing locus, so that it will have negligible effect on the behavior of the relays. More rigorous analyses have been given in previous papers.[4,5]

POWER SWING ON A FAULTED LINE

It can be shown that, during a power swing on a transmission line with two conductors short circuited together, as in Figure 18, the resultant current from faulted pair of conductors has only the fault current, and no swing component, and that the remaining pairs of conductors have a combination of the swing current and the fault current.

The following table is based on these premises and gives the swing and fault components of the current in the conductors at the end *S* and at the relay location *A*. Figure 18 shows the equivalent diagram of the system, and explains the terms Z_S, Z_r, and Z_F.

Current	Swing Component	Fault Component
I_1'........	$\frac{E_S-E_L}{Z_S}$........	0
I_2'........	$-\frac{E_S-E_L}{2Z_S}$........	$\frac{(a^2-a)E_S}{2Z_F}$
I_3'........	$-\frac{E_S-E_L}{2Z_S}$........	$-\frac{(a^2-a)E_S}{2Z_F}$

Distance relays are usually provided either with delta current or with double windings, so that the magnetic effect is the same as with delta current. The following are the currents supplied to the relays:

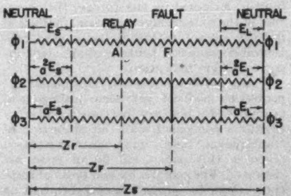

Figure 18. Simplified circuit of a transmission line with a line-to-line fault

$$I_1'-I_2'=\frac{3}{2}\cdot\frac{E_S-E_L}{Z_S}-\frac{(a^2-a)E_S}{2Z_F}$$

$$I_2'-I_3'=0+(a^2-a)\frac{E_S}{Z_F}$$

$$I_3'-I_1'=-\frac{3}{2}\cdot\frac{E_S-E_L}{Z_S}-\frac{(a^2-a)E_S}{2Z_F}$$

The potentials at the relay location can be derived in the usual manner subtracting the line drop from the generated electromotive forces

$$V_1'=E_S-I_1'Z_r=E_S-\frac{E_S-E_L}{Z_S}\cdot Z_r$$

$$\begin{aligned}V_2'&=a^2E_S-I'_2Z_r\\&=a^2E_S+\left(\frac{E_S-E_L}{Z_S}-\frac{(a^2-a)E_S}{Z_F}\right)\frac{Z_r}{2}\end{aligned}$$

$$\begin{aligned}V_3'&=aE_S-I_3'Z_r\\&=aE_S+\left(\frac{E_S-E_L}{Z_S}+\frac{(a^2-a)E_S}{Z_F}\right)\frac{Z_r}{2}\end{aligned}$$

The delta potentials can be derived from the Y-potentials as follows

$$V_{12}'=(1-a^2)E_S-3\left(\frac{E_S-E_L}{Z_S}-(a^2-a)\frac{E_S}{Z_F}\right)\frac{Z_r}{2}$$

$$V_{23}'=(a^2-a)E_S\frac{1-Z_r}{Z_F}$$

$$V_{31}'=(a-1)E_S+3\left(\frac{E_S-E_L}{Z_S}+(a^2-a)\frac{E_S}{Z_F}\right)\frac{Z_r}{2}$$

From the foregoing delta currents and potentials the impedance seen by the relays can be derived as follows. With a phase *2*- phase *3* fault the phase *12* relay measures $Z_{12}'=V_{12}'/(I_1'-I_2')$.

Hence

$$\begin{aligned}Z_{12}'&=\frac{(1-a^2)E_S-3\left(\frac{E_S-E_L}{Z_S}-(a^2-a)\frac{E_S}{Z_F}\right)\frac{Z_r}{2}}{\frac{3}{2}\cdot\frac{E_S-E_L}{Z_S}-\frac{a^2-a}{2}\cdot\frac{E_S}{Z_F}}\\&=\frac{2(1-a^2)E_S}{3\frac{E_S-E_L}{Z_S}-(a^2-a)\frac{E_S}{Z_F}}-Z_r\underline{/\phi}\\&=\frac{Z_S\left(1+\frac{j}{\sqrt{3}}\right)}{1+\frac{j}{\sqrt{3}}\cdot\frac{Z_S}{Z_F}-\frac{E_L}{E_S}}-Z_r\underline{/\phi_r}\end{aligned}$$

If

$$K=1+\frac{j}{\sqrt{3}}\cdot\frac{Z_S}{Z_F}$$

θ_S is the angle by which E_L lags E_S, ϕ_r is the phase angle of Z_r, ϕ_K is the phase angle of K, and R_V is the ratio E_L/E_S, then

$$Z_{12}'=\frac{2Z_S\underline{/\phi s+30^\circ}}{\sqrt{3}(K\underline{/\phi_K}-R_V\underline{/\theta_S})}-Z_r\underline{/\phi_r}$$

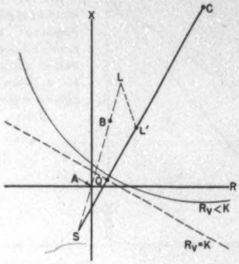

Figure 19. Locus of impedance seen by phase 1-2 relay during a line 2-line 3 fault with a power swing

The locus of Z_{12}' is a circle of radius

$$\frac{2R_VZ_S}{\sqrt{3}(K^2-R_V^2)}$$

and center

$$\frac{2KZ_S\underline{/\phi_S+30^\circ-\phi_K}}{\sqrt{3}(K^2-R_V^2)}-Z_r\underline{/\phi_r}$$

Similarly

$$Z_{31}'=\frac{2Z_S\underline{/\phi_S-30^\circ}}{\sqrt{3}(K\underline{/-\phi_K}-R_V\underline{/-\theta_S}}-Z_r\underline{/\phi_r}$$

where

$$K=1-\frac{j}{\sqrt{3}}\cdot\frac{Z_S}{Z_r}$$

whose magnitude is the same as before but with a negative phase angle. The locus of Z_{31}' is a circle of radius

$$\frac{2R_VZ_S}{\sqrt{3}(K^2-R_V^2)}$$

and center

$$\frac{2KZ_S\underline{/\phi_S-30^\circ-\phi_K}}{\sqrt{3}(K^2-R_V^2)}-Z_r\underline{/\phi_r}$$

which is a circle of the same radius as the Z_{12}' circle and displaced the same distance on the other side of the line impedance vector.

In the section on Power Swing Charts it was stated that, within the bounds of reasonable accuracy, the locus of the Z_{12}' and Z_{31}' impedances (Figures 11 and 12) could be drawn as a line bisecting at right angles the line SR' which was related to the total system impedance SR. This assumption is based on the following reasoning: referring to Figure 19, which corresponds to Figure 11

$$SQ=SC-CQ$$

$$=\frac{2Z_S(K-R_V)}{\sqrt{3}(K^2-R_V^2)}$$

$$\frac{2Z_S}{\sqrt{3}(K+R_V)}$$

If $K=R_V$, then $SQ=1/2SR'$, that is, Q bisects SR', hence $1/2\,SR'$, $=Z_S/\sqrt{3}\,K$. Now SC and the radius CQ tend to be infinite since they have $(K^2-R_V^2)$ in their denominators so that the locus will tend to be a straight line through Q which bisects SR'.

In practice $K>1$ and, on a line long enough to have power swing trouble, R_V would be equal to or slightly greater than unity, so that R_V would tend to be equal to K.

If $R_V<K$ the locus would be a circle with the center beyond C, but line capacitance would tend to curve it down towards the straight line. Hence in general the assumption of a straight locus is a reasonable one for a line long enough to warrant a check of this kind. As stated before, the error involved is negligible in predicting relay performance because the circle is so large that its periphery is substantially straight within the confines of the relay characteristic.

Conclusions

It is possible to determine the behavior of any form of protective relay under any system conditions by using the methods explained in the foregoing. Distance relays were used as an example because they combine the operating functions of most of the other relays and are more complicated than the others. By making such analyses not only can abnormal operations of distance relays be explained but applications of new relays can be made with greater confidence.

Superposition of the characteristics of the present standard types of distance relays upon these fault charts indicates that they are relatively free from incorrect operation if no power swing is present. It also has been shown that ground distance relays can be made more useful if properly connected.

Discussion

H. P. Dupuis (The Commonwealth and Southern Corporation, Jackson, Mich.): The author is to be complimented on his very complete and concise presentation of this paper.

The graphical method for determining the settings of step-type relays has been in use for a number of years and has been of much assistance to relay engineers. The procedure given by Mr. Warrington in this paper should further assist in making more accurate settings and in checking probable causes of incorrect operation and therefore is a useful contribution to the art of relaying.

Phase relay characteristics for line-to-line faults shown in Figure 1(C) are of special interest in analyzing the operation of certain impedance relays having greater reach along the resistance axis. For nearby faults, two or even three targets may show where only one would be expected. Also of considerable interest is Figure 3(B) showing the characteristics of phase relays on line-to-ground faults. As noted by the author, the operation of the phase relays on ground faults is of definite advantage but it has caused considerable confusion because of apparent incorrect target indication.

The use of distance relays for ground fault protection has not yet come into general practice but it is a very live issue for all relay engineers concerned with the protection of transmission lines, and the information given in this paper will be of great assistance. The complexity and costs of step-type relays for ground fault protection as compared with a simple induction-type relay, will deter their general adoption, especially since fast clearing of ground faults is not generally considered as necessary as the fast clearing of phase faults. In addition to faster clearing of ground faults, the advantage of step-type ground relays is the same as for phase relays in that they are almost immune to system changes.

Richard W. World (United States Bureau of Reclamation, Denver Federal Center, Denver, Colo.): One fault condition not covered by the author, which I believe is of interest, is a line-to-line fault on the opposite side of a Y-delta or delta-Y-connected transformer bank. A practical case is that of a substation without high-voltage circuit breakers, since from a recent AIEE committee report[1] it appears that the practice is not uncommon of relying on remote line relays for transformer protection.

Figure 1 of the discussion is a curve which we have developed from mathematical analysis, showing the shorter distance relay reach for low-voltage line-to-line faults as compared with 3-phase faults. It appears that a graphical method for this fault condition would be the same as for a line-to-ground fault on the high-voltage side, except that the impedance would have no zero-sequence component. In Figure 3(A) of the paper if *AF* were the impedance seen for a low-voltage 3-phase fault, then *AM, AN,* and an infinite impedance would be seen by the 3-phase distance relays for a line-to-line fault at the same location. Is this correct? It would be interesting to know the reach of ground distance relays for this low-voltage fault, which has no effect on the usual residual current ground relay.

REFERENCE

1. PROTECTION WITHOUT HIGH-VOLTAGE SWITCHING, AIEE Committee Report. *Electrical Engineering*, June 1949, page 520, and *AIEE Transactions*, part I, volume 68, 1949, pages 226–32.

A. R. van C. Warrington: With the method described in the paper it is possible to determine accurately just what a phase or ground distance relay will do under any fault or power swing condition. With this knowledge relays can be selected with assurance that they will operate correctly, and an analysis can be made quickly to determine the cause of misoperation of relays in use.

Mr. Dupuis calls attention to two cases where relays have not necessarily tripped wrongly but provided misleading information through their targets. By comparing the targets shown at both ends of the protected section, the true story can be found. For instance, in the first case cited by Mr. Dupuis, in Figure 1(C), if the impedance *SA* were slightly smaller, the tripping areas would intersect the circle causing three impedance relay targets, which would indicate a 3-phase fault, whereas at the other end of the section only one impedance relay target would show, indicating a phase-to-phase fault.

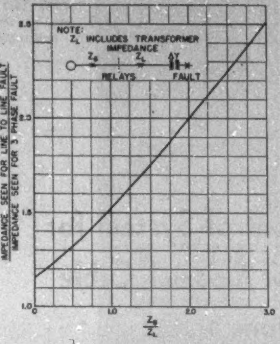

Figure 1. Reduction in relay reach for line-to-line faults on far side of delta-Y transformer bank

Reference to a diagram similar to Figure 1(C) would explain the true nature of the fault and would indicate the targets. In the past such an occurrence would have been construed as erratic operation of the targets.

The second case cited by Mr. Dupuis also shows how this method of analysis can be used to unravel target indications. Figure 3(B) shows that two phase relays may operate for a nearby ground fault while, at the other end of the line section, a ground relay and none of the phase relays will show targets. Again these indications may be misunderstood unless both ends are considered with reference to these diagrams.

I agree with Mr. Dupuis that ground distance relays are now a live issue as they are being used in increasing numbers.

Mr. World called attention to the fact that the paper does not cover the case of a fault on the opposite side of a Y-delta or delta-Y transformer. His analysis is correct for a 3-phase fault and his diagram is essentially correct for a system of homogeneous impedance.

There are obviously other conditions which could have been discussed but which could not be covered within the scope of a single Institute paper. However, these and other aspects of this subject should be covered, and it is to be hoped that other AIEE papers will be written on them using, if possible, a simple graphical method similar to that used in this paper.

B-1 Alarm and Control System for Remote Control of Coaxial Cable Stations

R. B. HEARN
MEMBER AIEE

LAURANCE A. WEBER
ASSOCIATE AIEE

THE *B-1* alarm and control system is an arrangement for providing remote control of stations on type *L* carrier telephone systems[1] over coaxial cables. There are two types of repeater stations: auxiliary stations which are spaced every 5-to-8 miles along the coaxial cable; and main stations which are spaced at intervals of 40-to-165 miles along the cable. Main stations perform many important functions such as supplying power to the auxiliary stations, receiving alarms from the auxiliary stations, providing line equalization, and cable switching. The alarm and control equipment is located in the main stations and permits remote control and supervision of many stations from one central control point. A typical coaxial maintenance and control section is shown in Figure 1(A).

Main stations are divided into groups, each group having one attended main station and one to ten unattended main stations. The attended main station exercises maintenance control over the unattended main stations in a group. Alarm registration devices, equipment for controlling the unattended stations, and equipment for indicating the conditions at any unattended station are installed in the attended station. Equipment for sending alarms, executing orders, and sending indicator signals are located in unattended stations.

Signals for the alarm and control circuits are transmitted between attended and unattended stations over channels obtained by compositing a 4-wire telephone order wire circuit which is provided for *L* system maintenance.

Figures 1(B) and 1(C) show the equipment of the *B-1* alarm and control system. Figure 1(B) shows the equipment used at the unattended station. The left-hand bay contains the relay equipment exclusive of that used to transmit signals. The right-hand bay contains the signaling equipment. Figure 1(C) shows the equipment at the attended station. In addition to the equipment shown in Figure 1(C), an additional bay similar to the signaling bay at the unattended station is provided.

Functions of System

The *B-1* alarm and control system has three distinct functions.

1. Alarm conditions at any unattended station are transmitted automatically to the controlling attended station indicating which station is in trouble and whether the alarm is of major or minor importance. The indication is on lamps and is accompanied by an audible alarm. This function is performed by the alarm circuit.

2. Orders or remote controls are transmitted to any unattended station by dial codes. Codes are available for 100 orders for each station. This function is performed by the director circuit.

3. One of the available orders causes equipment at an unattended station to send indicator signals back to the attended station. It is possible to indicate the condition of 168 circuits on a bank of neon indicator lamps in the main station. This function is performed by the indication circuit.

Composited Signaling Circuit

The signaling circuits are terminated at each end of the line section between two main stations by composited signaling terminals. A ground terminal is furnished at the end of each line section at or nearer to the attended station and a battery terminal is furnished at the other end. Three operating channels and a neutralizing channel are provided on a 4-conductor line. A typical layout is shown in Figure 2.

The first channel, shown in Figure 3, is a differential-duplex circuit used for transmitting alarms from all unattended stations to the main station. When an alarm condition occurs at any unattended station, the sending potential at that station is changed from battery to ground. This condition is repeated in each line section between the originating station and the attended station. When

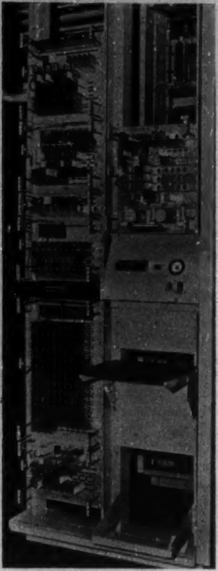

Figure 1(B) (left). Equipment at unattended station

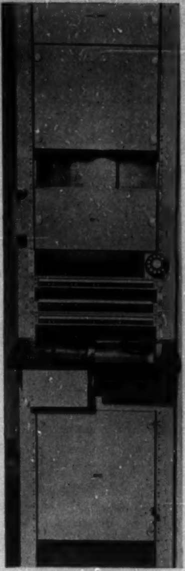

Figure 1(C) (right). Equipment at attended station

the attended station is ready to accept the alarm information, the sending potential at the attended station is changed from ground to battery which is likewise repeated into the next line section at each station between the attended and originating stations. On receipt of the battery signal, the originating station sends a code consisting of alternate battery and ground pulses. Both ends of the circuit are then restored.

The second channel is a differential-duplex circuit used for transmitting orders to the unattended stations and for sending synchronized stepping pulses for the indication circuit to the attended station.

The third channel is a 1-way polar circuit used to transmit indication signals to the attended station. The second and third channels are shown in Figure 4.

The fourth channel is used for neutralizing interference in the three operating channels. The neutralizing circuit duplicates the configuration and electrical constants of the operating channels, but is terminated in equal potentials obtained from potentiometers across the operating channel batteries. Differences in battery voltages at the two ends of a line section are partially compensated by this device. Because the operating channel balancing circuit is duplicated in the neutralizing channel large amounts of interference and ground potentials, either alternating or direct current can be tolerated by the system as the effect produced in the receiving relays due to extraneous currents in the operating channels is cancelled by a substantially equal current in the neutralizing channel.

Vibrating circuits are provided for receiving relays which are required to receive pulses except on the third channel where the retransmission of pulses is controlled by the second channel. The vibrating circuits increase the effective operating forces during the transition times when the circuits are most susceptible to interference, and they tend to correct signal distortion by lengthening short pulses and decreasing long pulses. Only one set of transfer contacts is avail-

able on polar relays and since a vibrating circuit is controlled through the contacts of the relay which it acts upon, it is necessary to operate additional relays when contacts free of other circuits are required. The windings of these other relays are made a part of the vibrating circuits. The arrangement used permits a voltage swing on the vibrating circuit equal to twice the available battery voltage. This simplifies the design problem when the available battery voltage is low.

The windings of two additional relays are included in the vibrating circuit for the receiving relay of channel two at the ground terminal. The first relay follows the operation of the receiving relay at all times. The second relay follows the operation of the receiving relay except when prevented from doing so by the closure of a holding circuit through the contacts of the receiving relay of channel three. The holding circuit is connected through the normally-closed contact of the second relay, so that when the second relay operates from its idle position the holding circuit loses control. The indication signals are thus synchronized with the stepping pulses at each main station. Two or more indication signals occurring in sequence can be combined at the indication sending equipment into one long signal which will open the holding circuit at the first ground terminal for the required number of pulses.

The relay controlling the indication pulses will operate to the opposite contact during the idle period if the holding circuit is opened. It is necessary therefore to have a means of restoring the relay to its normal position if the holding circuit is opened momentarily by a trouble on channel three. A slow release relay provides a restoring circuit after a short interval if the holding circuit has been reestablished through the contacts of the third channel receiving relay.

Alarm Circuit

When an alarm condition occurs in any one of the remote main stations, the alarm sending circuit associated with that station seizes the alarm channel (channel 1) and sends a d-c signal along the line toward the control main station. This signal is received and retransmitted at each intermediate remote station between the station originating the alarm and the main station. The receipt of this signal by the intermediate stations serves to inform the alarm sending circuits at these stations that the alarm channel is in use so that any alarm originating at these intermediate stations will be stored until the alarm channel is free. Receipt of this signal by the control station causes operation of relays in the alarm receiving circuit which send an answering steady signal in the reverse direction, that is, toward the remote station. This station interprets this signal as an indication that the alarm channel is functioning correctly and is not transmitting an alarm from another station. It thereupon transmits a series of pulses at a rate of ten per second. The number of pulses sent out indicates the particular station sending the alarm and whether the alarm is of major or minor importance. Figure 5 shows the alarm circuits in outline form for the control station and for the nearest remote station on one side. Additional remote stations contain identical equipment as that shown for the first remote station.

Figure 5. Alarm circuits — Channel 1

When an alarm condition originates at the remote station either a major *MJ* or a minor *MN* lead is grounded depending upon the class of the particular alarm. Each alarm source operates a particular alarm relay which in turn operates the seizure relay *SE* causing the alarm channel to be seized. The seizure changes the condition of the line, the line current dropping to zero or to a low value if small earth potentials are present. This change of line condition causes a signal to be sent to the *CX* signaling circuit at the main station where relays *CX1* and *R1* in that circuit and relay *L1* in the alarm receiving circuit operate. The alarm receiving circuit responds to this signal by operating relay *S2* which changes the line condition of the channel in the opposite direction sending an answering signal toward the remote station. When the signal is received at the remote station, it activates a pulse generator. The pulse generator supplies pulses at the rate of ten pulses per second to the *S1* relay and also to a local counting circuit. The pulses applied to the *S1* relay cause pulsed operation of the *L1* relay in the alarm receiving circuit. The local counting chain is arranged to stop the pulse generator when a particular number of pulses has been produced. Optional wiring to the counting circuit is different at each station so that the number of pulses which are sent out before the pulse generator is stopped is different for each station. The pulses received in the alarm receiving circuit drive another counting chain which registers the total number of pulses received, lighting an annunciator lamp and actuating an audible alarm in accordance with the meaning attached to the number of pulses.

When the pulsing is through, and the alarm information registered, the seizure signal is removed toward the control station. This results in the removal of the start signal from the line and the conditions revert to those encountered normally and the alarm channel is available for use by any other station having alarm conditions to be registered.

Director Circuit

When an attendant at the control station desires to perform some remote control action at any one of the remote main stations he dials a 3-digit code on the telephone dial associated with the sending director circuit. The first digit dialed corresponds to the station to which the order is directed and the second two digits represent the particular remote control action desired. Since 100 separate codes are available from 2-digit 10-pulse combinations a total of 100 orders is available for use at each of ten remote stations. Figure 6 shows the circuits for the director signals. In addition, Figure 6 shows parts of the indication circuits which also use channel 2, and which will be described in succeeding paragraphs.

When the attendant operates the dial key in the sending director circuit and dials the first digit he causes pulsed operation of relays *L1* and *S2* in the control station, and relays *CX2*, *R2*, and *L1* in all the remote main stations. All remote stations count the number of pulses contained in this first digit by means of local counting circuits driven from the *L1* relay in each receiving director circuit. In the particular remote main station to which the director signal was addressed, the local counting circuit is wired so as to respond only to the particular number which was dialed as the initial digit. When the receiving director circuit receives this first digit, it enables itself to accept the succeeding two digits which are dialed by the attendant.

The second digit dialed will again cause operation of relays associated with channel 2. Only the receiving director circuit

associated with the station to which the first digit was directed, however, will count the second digit. All other remote stations will ignore this digit. This second digit will be counted by the counting chain in this station, and a particular final relay out of a total of ten will be energized after the digit has been received. In a similar fashion, the third digit is received by the selected remote station and causes a ground to be applied to a particular contact on the final relay which had been operated as a result of the registration of the preceding digit. This ground, which can occur on any one of the 100 leads can be used to operate relays in a local circuit for any particular control function. Typical controls for the *L* carrier system are: start gas engine; start indication circuits; and reset pilot level sensitrol relays.

Indication Circuits

One of the orders sent by the director circuit is used to start the indication circuit. This circuit transmits automatically the condition of as many as 168 circuits at the remote station. These indication signals appear at the main station as lighted neon lamps arranged in a convenient bank in a keyshelf. Information about the circuits at the remote station is obtained by scanning a group of 168 leads and ascertaining whether particular leads are grounded or not. When a grounded lead is encountered in the scanning process, a signal is sent to the main station to light the particular neon lamp which is permanently associated with that lead in the receiving lamp bank. Since 14 of these 168 leads are used in checking the identity of the station and the correctness of the received display, there remain available 154 indication signals which may be used to determine the status or condition of circuits at the remote point.

Figure 6 shows the circuits associated with channel 2 for the indication circuits. In addition, Figure 7 shows the circuit associated with channel 3 for the indication circuits. Channel 2 which was used for sending director signals in the direction from the main station toward the remote station also is used for sending synchronizing pulses in the opposite direction when indications are being transmitted. The director signal which sets the indication circuit in operation, energizes a pulse generator which begins to send out dial pulses at approximately ten pulses per second. These pulses are used to operate a local scanning circuit and are also transmitted over channel 2 to the main station where they operate an identical scanning circuit. The pulses transmitted to the main station are sent by operation of relays *PF* and *S2* in the remote station and relays *CX2*, *R2*, and *L2* in the control station. Thus two identical scanning circuits are driven simultaneously from one pulse generator. The scanning circuit at the remote main station looks at each one of the indicator *ID* leads in turn and the scanning circuit at the control station connects to each of the neon indicator lamps in turn. When the scanning circuit at the remote station is looking at a particular *ID* lead, the scanning circuit at the control station is always connected to the particular indicator lamp associated with that lead.

Whenever, in the course of the scanning cycle, the scanning circuit encounters a lead which is grounded, it sends a signal (see Figure 7) over channel 3 to the control station. This signal, causes the particular indicator lamp to operate when the scanning circuit is looking at it. Channels 2 and 3 are interlocked in the ground terminal composite signaling circuit at the main station, as has been described previously, in order to make certain that the synchronizing pulses and the marker pulses occur simultaneously so that the correct lamp will always be energized.

The indicator lamp bank is arranged under a frosted plastic cover of standard letter size paper so that a permanent record or log of the condition of all important circuits for a particular unattended station may be made by the attendant simply by checking the printed form which is placed over the plastic cover.

Summary

The *B-1* alarm and control system provides means of supervising and controlling as many as ten remote stations in a maximum of four directions from the control station. The maximum distance between the most distant stations in a maintenance group is 1,650 miles which certainly exceeds the range in which remote stations can be serviced efficiently from a single maintenance center. The system presages increasing use of automatically-obtained information about isolated stations and stepped-up use of remote control signals for the telephone plant.

As the communication circuits in use increase in complexity, and the trend toward centralized maintenance effort continues, reliable alarm systems such as the *B-1* alarm and control system will be necessary for efficient use of the new developments.

Power Supplies for Coaxial Systems

H. H. SPENCER
ASSOCIATE AIEE

THE TYPE *L* broad-band carrier telephone systems are in extensive use over nationwide coaxial-cable networks. Some use has been made of these facilities for transmission of television programs. The closely spaced repeaters needed for these systems to maintain proper transmission of the signal frequencies, approximately every five miles for 0.27-inch and every eight miles for 0.375-inch coaxials, has made it desirable to transmit 60-cycle power to auxiliary repeaters over the same conductors as used for the higher frequencies, rather than have a separate power supply at each repeater. This paper describes the power-supply system used, its regulation, and some of the features employed to guarantee continuous service. Communication and television features have been described previously,[1-3] and in this paper will be referred to only insofar as they are affected by the power supply.

Constant-Current Power System

The power transmission system involves a circuit in which the primaries of the power packs at each repeater are arranged in series with the inner conductors of the coaxials to form a series feed from a power sending station. With proper loading to compensate for shunt capacity, all power packs in a transmission circuit receive substantially the same line current. By regulating this current at the source, constant power supply is obtained at each repeater. Figure 1 illustrates a typical span of auxiliary repeaters between adjacent power sending stations. At the left, a terminal station supplies power to its own repeater and, over coaxials *1* and 2, to six auxiliary repeaters with the power circuit looped at the sixth repeater. The remaining five repeaters of the span are supplied from the main station shown at the right of Figure 1. Power is supplied from this station to repeaters in both directions. The power section west of the main station is not looped at the last repeater which it supplies, but is carried to the next repeater and looped there through a looping filter. This is done to maintain current in all cable sections, thus facilitating testing, both in locating faults and also in establishing that the sending-end voltage has been removed before workmen are allowed to open the cable.

The number of repeaters supplied in a span between power sending points depends on several factors, chiefly: availability of existing Bell System buildings and personnel along the coaxial cable routes, need for dropping circuits at intermediate points along the route, and availability of commercial power service. Spans will be as short as 40 miles to permit dropping circuits, but will average about 100 miles and may be as great as 165 miles. From a power standpoint, the maximum span is determined by the safe voltage which may be applied at the source to obtain the required line current. At present, the maximum rms 60-cycle voltage which has been applied to the power separation filters at the power sending station is 1,700 volts, 850 volts to ground. A line current or between 430 and 500 milliamperes is employed to supply the power-pack primaries.

Repeater Power Pack

Figure 2 shows more detail of the power circuits at main and auxiliary repeaters, including the power separation filters which separate the carrier frequencies from the low power frequencies so that the former may be amplified and returned to the coaxials for transmission to the next station. The power pack at each repeater includes a transformer having two primaries, one in series with each side of the power circuit. Its secondaries supply a-c filament power at approximately 6.7 volts, and, through a rectifier, d-c plate at approximately 140 volts. The rectifier is of the metallic type with filters to reduce ripple voltages. A large electrolytic capacitor across the rectifier output provides a hold-over plate supply to the amplifiers to maintain carrier transmission during short interruptions of power supply, such as a two cycle outage in switching from a regular to an emergency source. The plate windings of the power transformer are in series, so that the resultant plate voltage is not affected by any unbalance in the current flowing in the two sides of the power loop so long as the average current in the loop remains the same. However, the filament windings are individual to each coaxial amplifier, and, to prevent unequal heater voltages in the event of unequal line currents in the two coaxials, these windings are connected through load balancing coils so that they are at substantially the same voltage. These coils are designed as low-pass filters to prevent crosstalk between amplifiers. The power circuit is grounded at the midpoint of the supply transformer for safety reasons; unbalanced current in the two coaxials may be caused by unequal leakage to ground, shorts in the coaxials, or as has happened in a few instances, by induced currents resulting from heavy earth fault currents from a ground high-voltage commercial power feeder in the vicinity of the coaxial cables. Cover switches are provided at all points of access to the power circuit to short out the power supply in case the maintenance forces fail to turn down power before opening covers.

The power circuit is treated as a unity-power-factor load. Loading is added as required to practically equalize the line current throughout the circuit. The primary current at each auxiliary station

is the vector sum of the series line current, the shunt current which flows through the capacities of the power separation filters, and the distributed capacity of the cable itself. Taps on the transformer primaries at each repeater provide adjustment for variations in power-pack outputs. The adjustment of these taps and the line currents required for the power circuit are determined on a trial basis. Shunt loading, applied only at the source, and series loading shown in Figure 2, are employed as required depending on the length and number of repeaters in the power section.

Regulation of Coaxial Current

The voltage applied at the source to give the desired line current to a power section is obtained by adjusting the taps of the power-control transformer, shown in Figure 2, to get the proper transformer step-up ratio when approximately normal alternating supply voltage is applied to its primary. The coaxial current then is regulated at the desired value by automatic control of the motor-driven continuously-tapped variable transformer. This is accomplished by holding a constant drop across resistance *L* which is in series with the transformer secondaries. With the line current normal, voltage relay *VR* maintains a neutral position. If, however, the line current is away from normal by about ±1.5 per cent, this relay makes its high or low contact to operate raise or lower relays. These relays connect power to a reversing-type a-c motor which is geared to drive the variable-transformer brush at a speed of one revolution per minute. The motor, of course, is controlled to change the supply voltage in the direction to return the line current to its regulated value.

Regulation of the line current is required chiefly to correct for changes in the load resistance due to temperature, and for fluctuations in the alternating supply voltage. Automatic regulation provides protection against overload such as might occur if a coaxial should open or become short circuited. Where the overload is insufficient to blow the supply fusing, the controls reduce the line current to normal by dropping the voltage to the necessary value. Where the short circuit is near enough to the main station to blow a supply fuse, the control circuit functions to turn the variable transformer to minimum voltage, so that replacement of the blown fuse cannot cause a line-current surge. Again referring to Figure 2, the loss of line current releases relay *NV* to remove the "raise" signal from relay *VR*, and provides a permanent lower signal until the maintenance forces throw a key and manually restore the line current.

Uninterrupted 230-Volt A-C Supply

The 230-volt a-c supply for the coaxial power circuit is provided from continuously-operated alternators rather than direct from the commercial service, to reduce the effect on carrier transmission caused by power service fluctuations and outages. The alternators are self-excited and are driven normally by induction motors from the commercial service and, during emergencies, by d-c motors from the station's 130-volt battery. With stable power-supply frequency, induction motor speeds are practically constant, and as the sets are self-excited and the loads are practically constant, the alternator output voltage normally is held within close limits and is affected very little by commercial-power voltage variations. The alternators further serve to insulate the coaxial power supply from any power-line high-voltage surges, lightning hits, or power-service harmonic interference.

The d-c motor is connected to battery whenever the alternator is operating, but is kept from supplying any appreciable power, while the a-c motor is driving, by

the insertion of a current-limiting resistance in its armature circuit. The field of the motor is connected to the battery side of this resistance. The setting of the field resistance is such that the counter electromotive force across the armature is practically equal to the battery voltage. Accordingly, when fast-acting relays short circuit the resistance in the armature circuit to cause the d-c motor to take over the drive, there is little or no inrush of armature current and, therefore, little change in alternator output. The d-c motor speed is unregulated and varies with the battery voltage, as the motor field rheostat remains at a fixed setting. As the battery is held within close limits to meet other station load requirements, the alternator output during emergency operation is well within a range for which the power-control circuits can maintain regulated coaxial-cable current.

Alternator Control

A simplified schematic of the 230-volt supply circuit is shown in Figure 3. As drawn, this circuit shows an alternator set ready to start, with its load being carried by an emergency alternator. The set is started with its d-c motor by operating the "start" key to bring in the current-limiting starter. When the alternator voltage builds up to its normal range, a voltage sensitive relay *LV*1 connected across the alternator output causes relay *MS* to operate and hold the d-c motor connected to battery. At the same time, relay *MS* causes relay *M* to disconnect ground from the winding of contactor *AR*, which releases and removes the short from resistance *AR*. This inserts resistance (*AR*) in the armature circuit of the d-c motor, limiting its driving power. Relay *M*, in operating, also connects the a-c motor to take over the drive of the set. The alternator now is ready to take over the load. This is accomplished by returning the start key to normal. This removes ground from the winding of relay *EC*, which releases and causes relays *A* and *E* to transfer the load from the emergency to the regular alternator. It may be noted that transfer of the drive from one motor to the other is controlled by relay *M*. With this relay operated, the set will be a-c driven; released, d-c driven. Operation of the "d-c mot test" key provides a manual means of motor transfer; release of relay *TR* or relay *MF* provides automatic transfer control.

Power Failure Transfer Control

The operation of relay *TR* is controlled by a voltage-sensitive relay *VR* connected to the commercial service through a rectifier and step-down transformer. This relay is adjusted, by means of rheostats *R*1 and *R*2 in series with its winding, to close its low contact *L* at supply voltages in the order of 85 per cent of the nominal service voltage value for the particular station. Above 85 per cent of normal line voltage, the slip in speed of an induction motor will be so small that the alternator output may be expected to remain within close limits during a-c drive. On closing its *L* contact in the event of low voltage, relay *VR* connects battery to operate relay *L* which locks operated to battery from contacts of timer *TD*. Operation of relay *L* removes ground from the *TR* relay winding to cause transfer to d-c motor drive. It will be noted that the *TR* relay winding receives its power from the commercial service through a transformer and rectifier. This provides a more rapid transfer of motor drive in the event of instantaneous outage of service voltage in that the *TR* relay releases from loss of power without waiting for the slower marginal-relay control cut-off.

Transfer back to a-c motor drive is delayed by timer *TD* after power is restored to normal, to prevent too many transfers with unstable power-supply voltage. In this respect, an additional feature is provided, requiring a return of the service voltage to above 90 per cent of the nominal value before transfer can be made to a-c drive. This feature consists of short-circuiting rheostat *R*2 with operated contacts of relay *L*, thereby increasing the current in the winding of relay *VR*. Under this condition, rheostat *R*1 adjustment is such as to cause relay *VR* to make its high contact *H* at the desired percentage of nominal voltage. When contact *H* has been operated long enough for timer *TD* to break the holding battery on relay *L*, relay *L* releases, causing relay *TR* to reoperate and transfer the drive back to alternating current. Release of relay *L* restores relay *VR* and the control circuit to normal.

A-C Motor Failure Transfer Control

Another motor-transfer control is provided in the event the alternator output should fall below its normal range for reasons other than low power service

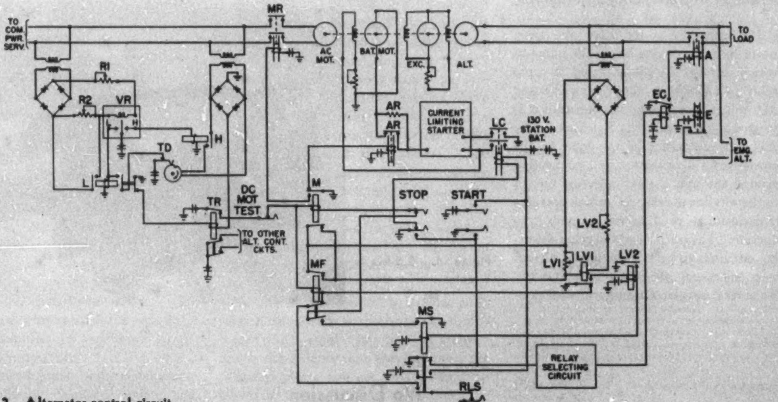

Figure 3. Alternator control circuit

voltage. For example, low line frequency without accompanying drop in line voltage would drop the alternator speed and output voltage, and no transfer in motor drive would result from the voltage control just described. Failure of the a-c motor could likewise drop the alternator voltage without the service voltage transfer control being affected. To care for these contingencies, rheostats *LV*1 and *LV*2, in series with relay *LV*1 across the alternator output, are adjusted so that relay *LV*1 will release at approximately 85 per cent of normal output voltage and cause relay *MF* to operate and open the grounded side of the winding of the *M* relay, thereby causing transfer to the d-c motor. Relay *MF* locks operated through closed contacts of operated relay *MS* to prevent transfer back to the a-c motor when the d-c drive brings the alternator voltage back to normal. When relay *MF* is operated, it also closes a short circuit around rheostat *LV*1, increasing the current in the winding of relay *LV*1 to make this relay reoperate and hold down to a lower value of voltage. This lower value of voltage is determined by the adjustment of rheostat *LV*2 and is used as an alternator cut-off control in case the d-c motor fails to maintain alternator output. If the d-c motor takes over the drive satisfactorily, relay *LV*1 is not released long enough to allow relay *LV*2 to release, as the latter is a slow-acting relay. Accordingly, the alternator will operate under d-c drive until an attendant releases the lock-up on the *MF* relay. The *MF* relay is kept from operating during power failure transfers by removal of battery from its winding during release of relay *TR*.

Transfer to Emergency Alternator

If, during d-c motor drive, the alternator output remains below the value at which rheostat *LV*2 is adjusted to cause relay *LV*1 to release, then relays *LV*2 and *MS* will release to stop the set until it is started again manually. Release of relay *MS* causes transfer of the load to the emergency alternator by connecting ground through a relay-selecting circuit to the winding of relay *EC*, which operates and causes relay *A* to release and *E* to operate. The purpose of the relay-selecting circuit is to permit the use of a common emergency alternator as a standby for several regular alternators, with control to prevent more than one load being transferred to the standby at one time. The emergency alternator is operated continuously at no load to reduce the outage time of the coaxial supply in the event of an emergency transfer. Manual transfer of the load to the emergency alternator may be accomplished by the "stop" and "start" keys whenever the regular alternators are to be shut down or operated for maintenance only.

Size of Alternators

Alternators usually are furnished on the basis of one alternator per pair of coaxials. In a station feeding power in one direction only, 1.5-kva alternators usually are used, but 2.5-kva and 5-kva sizes are available where it is desired to supply more than one pair of coaxials from the same machine. This usually is not done, however, in view of the large number of circuits affected if one machine should be down for maintenance and trouble should develop in another. In a main station feeding power to coaxials in two directions, 1.5- or 2.5-kva alternators are used, depending on the number of auxiliary repeaters supplied. A maximum of five alternators is required in such a station, for each 8-coaxial cable, one for each pair of coaxials, plus the common standby emergency alternator.

Unattended Operation

These power supplies are completely automatic for use in remote unattended stations, and because of this, they include alarms which are transmitted to an attended station to indicate abnormal conditions. Alarms are given if the coaxial current exceeds its normal limits, if drive is transferred to the d-c motor or if alternators fail along with other power plant alarms such as low battery voltage, battery fuse failure, engine failure, and so forth. Engine alternator standby for the commercial service generally is furnished, and, in unattended stations, the engine sets are started and controlled automatically. Station batteries also are charged automatically, using electron-tube-type rectifiers for battery voltage regulation. Station equipment such as order-wire circuits, alarms, and so forth, require 130-volt plate and 24-volt filament batteries. These are used, as has been previously stated, for 130-volt supply to the d-c motors and 24-volt supply for the various control circuits.

Terminal Equipment Power Supply

Power supplies for the terminal equipment used to bring telephone messages from the carrier down to voice frequency, usually are taken from the regular terminal station 130- and 24-volt plants. Particular care is taken in distributing these battery supplies, to prevent loss of service through accidental grounding, and to subdivide the fusing so as to reduce the number of circuits affected by the loss of any battery discharge fuse.

Power Supplies for Microwave Relay Systems

H. M. WARD
NONMEMBER AIEE

Synopsis: The establishment of microwave relay systems, carrying large numbers of separate telegraph communication channels on a single radio circuit and having relay stations located every 30 or 40 miles, usually in remote country districts, has put a premium on dependability of power supplies. This paper describes the facilities that have been provided for regular and fall-back power supplies for the Western Union radio-beam triangle which interconnects New York, Washington, and Pittsburgh. Interruption of the regular commercial a-c supply at any point causes the radio beam to be switched, without any effect on its operation, to a-c power supplied from battery-fed vibrators. Simultaneously, an engine generator unit is started and takes over the load automatically as soon as it has reached a steady operating condition. The paper includes a brief discussion of operating experience.

MORE THAN a century ago, Samuel F. B. Morse transmitted the words "What hath God wrought!" from Washington to Baltimore, and thus became the first individual to make practical use of electric energy in the communications field as a substitute for physical exertion. For many years thereafter, simple primary-battery plants sufficed as the fundamental source of power, without which there would have been no telegraph industry. Subsequent improvements in the speed and efficiency of telegraph operations brought about greatly increased demands for power and have made the requirements as to stability and reliability much more exacting. It is the microwave radio-relay system, however, with its inherent capacity for large numbers of communication channels on a single circuit, that has emphasized the necessity for power supplies of maximum continuity and dependability.

In a microwave radio-beam system such as that built by Western Union, the volume of traffic on a radio beam, and hence the importance of the circuit, far exceed that of anything previously used in the telegraph industry. Furthermore, completely automatic operation of all relay stations, except during prolonged operation on emergency power, was essential as a fundamental requirement. The relay stations are substantial in number and are so widely scattered that the cost of providing attendants at each station on a 24-hour basis would have been prohibitive. Therefore, the importance of maintaining continuous operation, and the fact that each relay station would have to function entirely without human aid at all times, in all kinds of weather, made extreme reliability one of the prime objectives in the design of the power-plant equipment.

The Power Supply Problem

Radio beam "terminal" stations are located in cities where dependable power supplies already exist, but the "relay" stations, almost without exception, are located in remote country districts where the commercial power supplies are subject to frequent outages due to line breaks caused by ice and wind storms. The radio-beam equipment was designed for operation on 115-volt 60-cycle a-c commercial power. However, since a power interruption of even a fraction of a second would cause disturbance in the beam signals that would persist for an appreciable period of time—even after power is restored—it was essential to provide each relay station with auxiliary power equipment which would function so quickly and so dependably that any failure of the primary power sources would have no effect on the radio-beam operation.

From previous experience it was known that automatic transfer switch operation could be achieved with an interruption of only about 0.05 second. It also was known that the addition of capacitors in the plate supply units of the radio equipment would make continuous operation possible during interruptions of more than twice that interval. The problem, therefore, was to provide an auxiliary source of 115-volt 60-cycle alternating current which would function in less than 0.1 second after a fuse blew or a tree fell over the power supply line.

The Complete Power Plant

The major components of the power plants installed at all relay stations of the radio-beam system are shown in Figure 1. Commercial 115-volt 60-cycle a-c power service is used as the normal source of supply for operating radio equipment, battery-charging rectifiers, station and tower lights, oil-burner motors, and other miscellaneous loads. An engine generator is provided as the prime emergency power supply for protection against prolonged power failures. Vibrator units, operated from a storage battery, are provided as the initial "instantaneous" reserve source of alternating current to maintain radio operation during the early stage of a power interruption, until the engine generator has started and has reached a steady operating condition.

In the event of failure of the regular service, or of a drop in voltage from the normal 115–120-volt level to below 102 volts, the "secondary" relay-controlled transfer switch almost instantaneously connects the storage battery to the input side of the two vibrator units and transfers the radio load to them. Simultaneously, the "main" relay-controlled transfer switch is set to start the engine-driven generator, and to switch the load

to it just as soon as the latter comes up to full speed and voltage, which may be 30 seconds or more after the initial operation. Actual starting of the engine is delayed for approximately 15 seconds in order to avoid unnecessary starting during extremely short power failures. If for any reason the engine should fail to start, the radio load would remain on the vibrators.

Simultaneously with these operations, special signals are automatically transmitted to each terminal to indicate that a power interruption has occurred and whether the load is being carried on the vibrator unit or the emergency engine. These fault tone signals are sent by a code-keying unit, operating over the service channel of the radio-beam circuit.

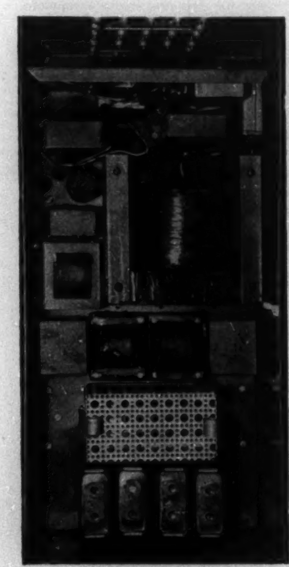

Figure 2. Vibrator unit

When regular power is restored, the load is transferred back automatically to that service; the engine unit is shut down, and the signals to the terminal stations are restored to normal. Here again, however, actual return to regular power is delayed for about five seconds after the commercial service reaches a minimum value of 108 volts, in order to make sure that the restoration is reasonably permanent. It often happens that, in the case of a power failure resulting from a short circuit or a grounded transmission line, the power-station attendant will make one or more attempts to reclose the circuit breaker feeding that line, only to have the breaker trip out again if the fault has not burned clear. The slight additional delay in transfer back to normal service almost entirely eliminates unnecessary switching operations and restarting of vibrators and engine unit under such conditions. Regulating transformers are interposed between the secondary transfer switch and the radio equipment in order to correct for variations in the commercial-service, engine-unit, and vibrator voltages.

Each station is provided with a small oil burner for heating purposes, not only to provide comfortable working conditions during emergencies, but to prevent condensation on radio and power equipment which could interfere with normal operation. The heating plant normally is operated so as to prevent the inside temperature dropping below 40 degrees Fahrenheit. This has the added advantage of facilitating the starting of the engine unit and preventing loss of battery capacity at excessively low temperatures.

Vibrators

The vibrators, which normally are intended to carry the radio load only until the engine unit has started and attained a steady operating condition, are big brothers to the units used for automobile radio operation, and are the largest size available which have been in use long enough to establish a satisfactory record of reliability. (See Figure 2.) Each vibrator has an output rating of 750 volt-amperes of 115-volt 60-cycle alternating current, and delivers its full-capacity a-c output almost instantaneously after closing of the d-c input circuit. Inasmuch as the radio load for a relay station, sending and receiving in two directions, is slightly in excess of 1 kva, it was necessary to divide the load between two 750-volt-ampere vibrator units. The units are supplied from the storage battery which is kept fully charged at all times.

Engine Generator Units

Inasmuch as remote-controlled automatic engine-generator units had been used by the thousands during the war in various branches of the armed services, there was considerable choice in the selection of such equipment. Various models produced by five of the larger manufacturers were inspected and compared, and a design worked out which incorporated the various features of the different makes that were considered essential for the radio-beam service. Four-cylinder gasoline engine drive (Figure 3), was selected in preference to a single or 2-cylinder diesel engine for two major reasons. First and foremost was the conviction that more reliable starting under cold weather conditions would be assured, particularly with unattended operation. Secondly, it appeared probable that the operation, adjustment, and emergency repair of gasoline engines would be more familiar to the average maintenance man because of similarity to the ordinary automobile engine. Use of the individual manufacturer's standard arrangement of starting and protective controls was adhered to so far as practicable, since these invariably had been used on a sufficient number of units to insure that basic faults had been eliminated.

The engines are radiator cooled. Two motor-operated louver openings are provided in the building wall for venting the heated radiator air and for admitting fresh cool air. The radiator-air exhaust opening is located directly in front of the engine; a canvas duct is provided between the front of the radiator and the opening to direct the air flow and to insure maximum discharge from the room, particularly during the summer months. Protective hoods are provided on the outside to prevent drifting snow, ice, or sleet from plugging the opening or interfering with the operation of the louvers, Figure 4. Only a very coarse 1/2-inch mesh screen was specified, to further reduce the possibility of restricting the air flow, either by the screen itself or as a result of snow or ice being deposited on the screen. Various protective devices, to shut down automatically the engine in the event of overheating, improper lubrication, or operation at excessive speed, are provided.

The alternator is equipped with a special voltage regulator, developed by the Electric Machinery Company. This voltage regulator has no moving part or contacts; this should reduce operating difficulties from such sources to a minimum. The engine governor is capable of maintaining a speed within limits of one per cent maximum variation at any given constant load, and four per cent maximum change between no load and full load.

An underground gasoline-storage tank of 120-gallon capacity is provided at each of the normal 1-beam stations. This will provide for about five or six days continuous operation, which is considered adequate to allow time for replenishment, even under severe weather conditions. The quantity in storage is limited purposely in order to minimize the possibility of gum formation which will occur when gasoline is stored for periods in excess of one year. Such gum formations easily could clog up the carburetor or fuel pump and cause failure of the plant to function, without prior warning.

Battery and Charging Rectifiers

In the majority of relay stations where only one radio beam is involved, a 57-cell 100-ampere-hour-capacity storage battery is used to supply the d-c input to the vibrator units. A somewhat larger battery is provided at stations such as Neshanic, where additional load is imposed by extra beam circuits. The battery is kept on trickle charge from a regulated-output selenium rectifier, developed primarily for this project. This rectifier maintains a constant voltage on the battery regardless of supply voltage variations within limits of 90 to 130 volts, so that the battery is kept fully charged at a rate just sufficient to offset internal losses. When the battery is used during a power failure, the charging rate is increased automatically until the battery is restored to a fully charged condition, at which time the trickle rate again prevails. The rectifier also is designed with inherent characteristics which prevent overloading and burning-out of the rectifier stacks or transformer.

A separate battery with rectifier charger is provided for starting the engine-generator unit.

Control Equipment

The major portion of the transfer switching and control equipment is incorporated on the main control panel, Figures 5 and 6, and is mounted immediately adjacent to the engine unit. This panel is enclosed in a metal cabinet with hinged double doors, front and back, to facilitate access. The two voltage-control relays, which constitute the "brain" of the plant, are mounted on rubber supports fastened to the side of the cabinet, to prevent vibration or jars from affecting their operation. Connections from the voltage-control relays to the panel are made through multiple-conductor plugs and receptacles to facilitate testing, removal, and replacement of the units. The upper control relay, shown on the left side of the cabinet in Figure 5, provides the signals required for starting and stopping the unit and for operation of the main transfer switch. The lower unit controls transfer of the radio load to and from vibrator operation.

The voltage-control relays were designed especially for this project, since nothing was commercially available which would provide the degree of sensitivity and other characteristics desired. The alternating voltage to be monitored is applied to a small bridge-type selenium rectifier, with a 75-microfarad capacitor

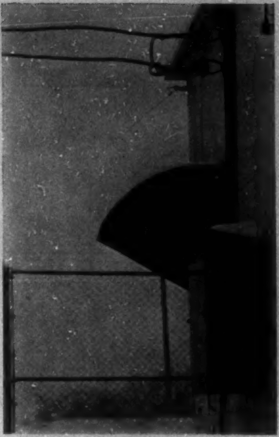

Figure 4. Air intake hood and power service entrance meter cabinet, gasoline tank

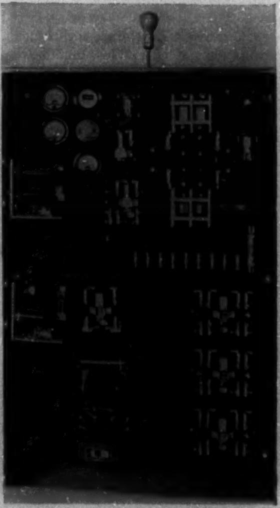

Figure 5. Main control panel, front

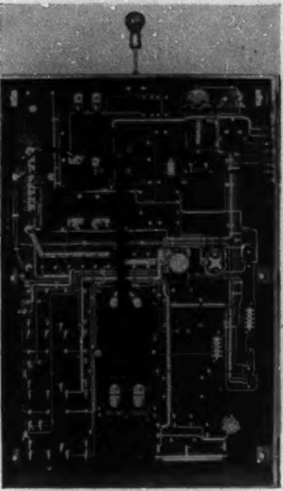

Figure 6. Main control panel, rear

across the d-c output of this rectifier as a filter. Variations in the alternating voltage are reflected directly in the direct output voltage of this small rectifier. A Western Union *41-C* relay, standard except for armature air-gap and contact-spring adjustments, is used to detect these variations. The two voltage-control relays are essentially identical except for the method used for obtaining the different time delay desired on the reclosing operation. In one, charging of a capacitor through a fixed resistor provides the desired 5-second delay; the other, shown in Figure 7, utilizes a small synchronous-motor-driven cam to provide a 1-minute delay, to give time for the engine unit to attain stable operation. Toggle switches are provided to by-pass the control relays, so that they may be tested and adjusted without unnecessary transfer of load to the engine unit or vibrators. A pilot light at the top of the control cabinet indicates when any of the special test switches are not in normal position for full-automatic control, to guard against the maintenance man inadvertently leaving the station without protection.

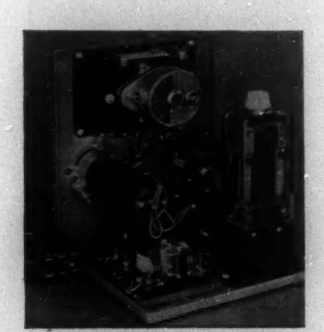

Figure 7. Voltage control relay for secondary transfer switch control

A special portable test set was designed for checking the adjustment of the voltage-control relays. Because of normal manufacturing variations in the small selenium-rectifier stacks, resistors, and other components, it is essential that each *41-C* relay be checked and adjusted in conjunction with the actual unit in which it is to be used. The relay test set provides a variable alternating voltage and an a-c meter, together with cord and plug connectors and indicator lights, so that the *41-C* relays may be checked conveniently in the required manner, without interference with operation of the radio circuit.

Meters on the main control panel show station load, voltage and frequency of outside power, engine, and vibrator units, and provide ready means for checking operation of the plant. An elapsed-time meter maintains a continuous record of hours of engine operation and shows whether any failures of regular power have occurred between inspections. A control switch is provided which permits testing of the engine unit either at no load or under load, simulating an actual power failure.

Also included on the main control panel are fuses for protection of load and control circuits, engine unit circuit breaker, auxiliary protective relays, and a selenium rectifier for charging the engine-starting battery. This battery is normally kept on a slow trickle charge in order to maintain it at full capacity. A higher charging rate is available from the rectifier for use if required.

The rectifier and its control components are housed in a rack cabinet, Figure 8, which also is used for mounting circuit breakers in the d-c input circuits to the vibrator units and the a-c input to the regulating transformers. The two vibrators and two regulating transformers required at the average 1-beam station are housed in this same cabinet, to simplify the installation of equipment. The main control cabinet, associated with the engine unit, and the rectifier cabinet were completely assembled, wired, and tested before shipment to the station. It then was necessary only to put these two units in place, to provide interconnections between them, and to the radio equipment, power service entrance switch, engine unit, and lighting cabinet, to complete the installation. Since many of the relay stations were in isolated locations, material savings in installation costs were thus effected.

Terminal Station Power

Because the terminal stations are manned 24 hours a day, the radio-system power facilities at these points are of a more usual type than described in the foregoing. Existing emergency supplies were utilized where available; vibrators were installed to serve as an instantaneous source of alternating current where an existing battery reserve was available. The same type of voltage-control relay as used in the relay stations was utilized at the terminal stations to control transfer of the radio load from regular to vibrator

power. The regulating transformers and vibrators, voltage control relays, transfer switches and associated protective circuit breakers, and alarm equipment for a two-beam terminal are housed in a rack cabinet such as shown in Figures 9 and 10.

Operating Experiences

The preceding general description of the radio-beam power plants and some of the considerations which affected their design, necessarily lacks considerable detail regarding such items as the engine-starting control and protective devices, generator voltage regulators, radio shielding, power distribution to radio equipment on the tower, and actual circuit diagrams. Rather than attempt to describe these various details, it would seem more desirable to present a brief resume of the operating results experienced to date with the power equipment of the radio-beam system.

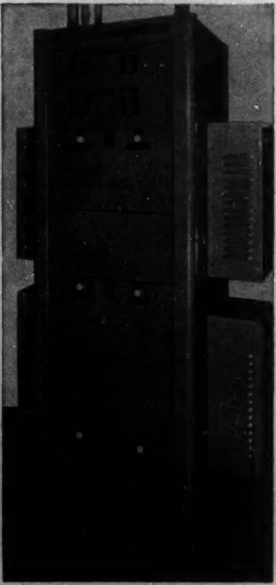

Figure 9. Terminal-station power equipment cabinet, front view

The New York–Philadelphia circuit was put into actual traffic operation late in 1947. The New York–Washington installation was completed and put into traffic operation on a trial basis during February, 1948. The New York–Pittsburgh and Washington–Pittsburgh circuits were completed and operated under test conditions a few months later. Operation was continued until late August, 1948, when regular operation was discontinued temporarily to permit changes in tower construction incidental to the installation of additional television channels between New York and Philadelphia, and to make adjustments in radio equipment, which operating experience had proved desirable. This, in effect, constituted the initial field trial of the power plants.

The emergency engine at Neshanic carried the station for a continuous period of over nine days, following the great ice storm of January 1–2, 1948. During this period, all power lines in the vicinity were down due to the storm, as were also all open-wire telegraph circuits between New York and Philadelphia. However, the radio system continued to function throughout the emergency and to provide reliable circuits for traffic service. Later, while the New York–Washington circuit was carrying traffic on a fairly regular basis, accurate records of operation were kept.

Table I shows the number and duration of power-supply failures occurring at each of the terminal and relay stations on that one circuit during the 3-month period between May 1 and August 1, 1948.

There was no interruption of the radio-beam circuit during that period, and no failure of the power equipment to function, indicating a high degree of reliability.

Subsequently, during a widespread snow, ice, and rain storm on December 15–16, 1948, at least 16 separate power failures occurred, affecting 10 of the 18 relay stations on the three beam circuits comprising the New York–Washington–Pittsburgh triangle. As many as six of these stations were operating on emergency power at a time, making it difficult for terminal station attendants to correctly interpret and accurately log the multitude of alarm signals being transmitted. Table II indicates the number and duration of failures, as accurately as could be determined from the log and subsequent detailed reports submitted by the maintainers. It will be noted that the outages of the commercial power sup-

ply add up to the rather astonishing total of approximately 150 hours.

Operation of the power-plant equipment was not perfect in all these instances, as there were two rather serious outages of the beam circuit caused by loss of power. One of these was caused by a regulating-transfer circuit breaker opening at the instant the load was transferred back to regular power, apparently because of faulty circuit-breaker operation, or because there was a current surge larger than had been designed for. In two other instances, these circuit breakers failed to function properly, but in these cases the maintainer was present and closed the circuit breaker immediately. Higher-capacity circuit breakers subsequently have been substituted at all stations.

In the other beam interruption, actual failure occurred because of a combination of circumstances. Here, the engine unit failed to start, and at the same time, the keying unit associated with the radio fault-tone alarm system failed to function, so that no one knew the power had failed until actual interruption of the beam occurred. Subsequent investigation showed that the station operated satisfactorily on battery power for at least nine hours after the regular power failed. Failure of the engine to start was apparently due to the exhaust pipe opening being completely clogged with ice, in spite of the precautions which had been taken to prevent such an occurrence. This constituted the only major interruption of the beam caused by lack of power during this entire interval.

In another case, the radio load remained on battery for two hours before being picked up by the engine unit, which then operated satisfactorily until the end of the power failure five hours later. There was no interruption to the radio beam.

What happened to the power unit only can be surmised from the fact that there were ice and carbon deposits around the exhaust pipe and muffler joints, quite similar to what were found in the previously described failure.

The operation of the power plants at the various radio-relay stations has been very gratifying. The reliability already demonstrated gives ample assurance that lack of power will not destroy the advantages of microwave radio beams for operation through fog, sleet, ice storms, and lightning, at times when these same elements may completely paralyze commercial power supplies.

No Discussion

A Microwave Communication Relay System

WILSON P. BOOTHROYD
NONMEMBER AIEE

HAROLD J. CHURCHILL
NONMEMBER AIEE

Synopsis: This paper describes the design of a microwave radio relay repeater suitable for use in communication systems requiring low distortion repeaters. The modulation bandwidth is approximately 500 kc for the illustrated design. The repeater employs negative feedback, and features extreme simplicity of electrical and mechanical design.

AT PRESENT, two general types of repeaters are in common use in the field. They are the subcarrier-type of remodulating repeater and the heterodyne-type repeater. Both types have features of excellence but are usually more complex than may be necessary for general communication service. The repeater to be described is advanced as an application and extension of techniques in related engineering fields to radio relay systems.[1,2]

This radio repeater is based on the use of a form of locked radio frequency oscillator. An incoming, frequency modulated, radio frequency carrier is used to cause a deviation of the oscillator output signal in accordance with the modulation of the incoming carrier. The oscillator signal is radiated as the repeater output signal. Figure 1 is a block diagram of a typical equipment. With the switch S open, the circuit is recognized as a conventional heterodyne receiver with the detected modulation of the incoming carrier appearing at the video amplifier output as a video signal. With the switch S closed this video signal is applied to the radio-frequency oscillator so as to cause its output signal to be frequency modulated in the same sense as the incoming carrier. Closing switch S thus closes the loop of a negative feed-back amplifier, and a study of the repeater performance can be made on the basis of feed-back amplifier analysis.

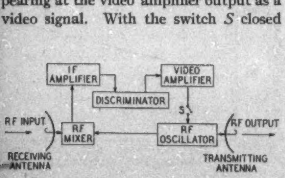

Figure 1. Block diagram of repeater

The performance of this type of repeater is measured by the accuracy with which the radiated radio-frequency oscillator signal corresponds to the incoming carrier signal in both magnitude and phase of modulation. The application of feedback in this repeater is operative in two major ways to minimize the distortions ordinarily encountered. First, the feedback decreases the distortion of nonlinear circuits, such as the control voltage versus output frequency characteristic of the radio-frequency oscillator. Second, the deviation of the intermediate frequency signal of the amplifier, which is the difference between the incoming carrier and the radio-frequency oscillator deviations, is small, so that phase and amplitude distortions in the intermediate-frequency amplifier are minimized. Other salient features of the repeater will be considered after an analysis of some general feed-back amplifier requirements.

General Feed-back Systems

A natural starting point in the analysis of the repeater is the standard inverse feed-back amplifier block diagram[3] shown in Figure 2.

$$E_o = \mu E_{IN} - \mu\beta E_o$$

where

μ = forward gain of the amplifier
β = fraction of E_o applied to amplifier input

$$E_o(1+\mu\beta) = \mu E_{IN}$$

$$\frac{E_o}{E_{IN}} = \frac{\mu}{1+\mu\beta}$$

The negative sign is used on the second term because this is an inverse feed-back system.

As applied to the repeater of Figure 1, the total voltage at the output of the amplifier is applied as a frequency control voltage to the local oscillator; therefore β equals 1, and the transmission equation becomes

$$\frac{E_o}{E_{IN}} = \frac{\mu}{1+\mu} \qquad (1)$$

In analyzing the repeater we prefer to consider the modulation on the incoming carrier as E_{IN} and the modulation of the radio-frequency oscillator output signal as E_o. It is further assumed that the modulation characteristics of the radio-frequency oscillator in each repeater shall be identical.

Equation 1 is the basic transmission equation of the system upon which the final calculations will be based. μ, the forward gain of the system, should be high in order that E_o/E_{IN} will approach unity. This ratio must be very close to one in order to make it possible to relay the modulation through multiple repeaters without serious loss of modulation. In any feed-back system, however, it is necessary that the feed-back factor $\mu\beta$ be less than one when the phase shift reaches 180 degrees. This is known as Nyquist's criterion.[4]

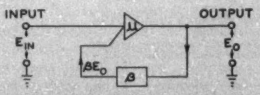

Figure 2. Basic feed-back diagram

Paper 49-158, recommended by the AIEE Communication Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer General Meeting, Swampscott, Mass., June 20–24, 1949. Manuscript submitted March 22, 1949; made available for printing April 29, 1949.

WILSON P. BOOTHROYD and HAROLD J. CHURCHILL are both with the Philco Corporation, Philadelphia, Pa.

Design of the Feed-back System

It is known from this criterion that an amplifying system will not oscillate if the magnitude of the amplifier forward gain at the 180 degree phase shift frequency is less than unity. The specifications for this repeater system require, in addition, that the ratio of E_o/E_{IN} with feedback shall be as nearly constant as possible throughout the desired modulation frequency range. In order to meet this last requirement it is usually desirable that the ratio $\mu/(1+\mu)$ should have an initial value at low frequencies, very near unity. In the following discussion, μ will be considered as a vector having both magnitude and phase components.

Figure 3 is a vector plot of the ratio $\mu/(1+\mu)$. In the first quadrant Figure 3(A) (phase shift of the μ circuit under 90 degrees) $\mu\underline{/\theta_1}/(1+\mu)\underline{/\theta_2}$ must always be less than unity since the real component of $\mu\underline{/\theta_1}$ is positive. Therefore the ratio of E_o/E_{IN} at low frequencies (where the phase shift is under 90 degrees) is less than unity, but will approach this value when the magnitude of μ is large. In the second quadrant (phase shift in the μ circuit between 90 and 180 degrees) $\mu\underline{/\theta_1}/(1+\mu)\underline{/\theta_2}$ will exceed unity if the real component of $\mu\underline{/\theta_1}$ is less than $-.5$. This is shown in Figure 3(B) and is undesirable, as this condition reveals regeneration within the amplifier. $\mu\underline{/\theta_1}/(1+\mu)\underline{/\theta_2}$ will be less than unity if the real component of μ/θ_1 is greater than -0.5. This is shown in Figure 3(C) and is the desired condition. Since both the magnitude and phase of the vector μ are functions of frequency, we are interested in a plot of the locus of the vector μ for all frequencies in the passband.

At this point it must be noted that a repeater as shown in Figure 1, involving both frequency modulation and amplitude modulation circuits as a part of the feedback loop, is unusual when analyzed to determine the parameters of the basic feed-back circuit. For example, the forward gain of the repeater is given by the equation

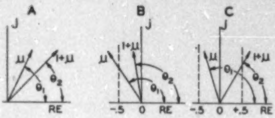

Figure 3. Plot of vectors μ and $1+\mu$

$$\frac{A_{osc}}{A_{disc}}\times G=\mu \tag{2}$$

where

A_{osc} = deviation characteristic in megacycles per volt of control voltage of the radio-frequency oscillator.

A_{disc} = discriminator characteristic in megacycles per volt of the video signal output of the discriminator, at the maximum carrier level provided by the intermediate-frequency amplifiers and limiters.

G = gain of the video amplifier circuits.

Since the A terms are constants not affected by the modulation frequency in the ideal case, the G term determines the relationship of the magnitude of μ to the modulation frequency. For reasons which will be developed later, the video amplifier must be a very narrow band amplifier with a bandwidth of approximately 1.3 kc. Thus the response of this amplifier may be taken as determining the magnitude of μ in accordance with equation 2. However, the phase angle of the μ circuit is determined by the complete amplifier. The phase characteristic calculations for a typical repeater composed of the circuits noted are shown in Table I. In these calculations, it has been assumed in each case that the carrier frequency is centered on the intermediate-frequency amplifier response, and that only envelope delay need be computed. This is not rigorous, but appears to be a necessary assumption in this first calculation. The video amplifier bandwidth is substantially less than the modulation frequencies tabled, therefore the phase shift of this amplifier is entered as a constant 90 degrees in the table. Figure 4 is a plot of the total phase shift taken from Table I. We can now progress to a determination of actual circuit values for a desired repeater performance characteristic.

Table I. μ Circuit Phase Response

Stage	Modulation Frequency 50Kc	100Kc	200Kc	500Kc	1Mc	1.75Mc
Intermediate frequency input stage (Double tuned, critically coupled, pole separation 16 megacycles)	0.32	0.64	1.28	3.20	6.5	11.7
6 Intermediate frequency stages (Double tuned, critically coupled pole separation 21 megacycles)	1.26	2.52	5.04	12.60	27.6	52.2
Discriminator (Pole separation 10 megacycles)	0.55	1.10	2.20	5.50	10.9	19.7
Discriminator (Reactance-capacitance output)	0.18	0.36	0.72	1.80	3.6	6.3
Narrow band amplifier (1.3 kc)*	88.50	89.30	89.50	89.70	89.90	90.00
Totals	90.8	93.9	98.7	112.8	138.5	179.9

*Note: In initial calculation when this bandwidth is not known, the amplifier phase shift can be entered as a constant 90.0 degrees.

Typical Design Calculation

It has been pointed out that the response of the video amplifier of the repeater is a very narrow band compared to the bandwidth of all other circuits. It is therefore the determining response of the gain versus frequency characteristic, and if the stage be a simple resistance-capacitance circuit (without peaking) then

$$\frac{\mu}{\mu_{max}}=\frac{1}{\sqrt{1+\left(\frac{f}{f_2}\right)^2}} \tag{3a}$$

where

f_2 = the cutoff frequency of the amplifier (3 decibels down)

μ_{max} = gain of amplifier at frequency 0 cycles per second

when

$$\frac{f}{f_2}>10$$

$$\frac{\mu}{\mu_{max}}\doteq\frac{f_2}{f} \tag{3b}$$

From Figure 4 we derive that the phase shift in radians for a frequency f (megacycles) is expressed by

$$f=1.10\theta-1.64 \tag{4}$$

in the region 0.5 to 1.0 megacycles.
From equations 3 and 4 we get

$$\mu\cos\theta=\mu_{max}\frac{f_2\cos\theta}{1.10\theta-1.64} \tag{5}$$

where

μ = the forward gain of the circuit at a frequency.

θ = the phase shift in radians at the same frequency.

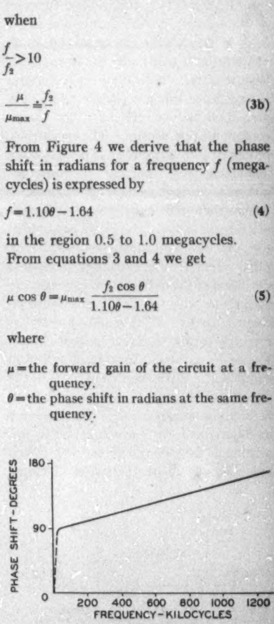

Figure 4. Plot of Table I

Table II. Repeater Tracking Coefficient

Frequency Kc/Second	$\mu/\underline{\theta_1}$	$(1+\mu)/\underline{\theta_2}$	Tracking Coefficient Per Cent	Degrees
0	$499/\underline{0^\circ}$	$500/\underline{0^\circ}$	99.80	0
1	$396/\underline{40.3^\circ}$	$396.76/\underline{40.21^\circ}$	99.80	0.09
10	$64.3/\underline{83.10^\circ}$	$64.43/\underline{82.22^\circ}$	99.80	0.88
50	$13.0/\underline{90.80^\circ}$	$13.024/\underline{86.40^\circ}$	99.81	4.40
100	$6.50/\underline{93.90^\circ}$	$6.509/\underline{85.08^\circ}$	99.86	8.82
200	$3.25/\underline{98.70^\circ}$	$3.253/\underline{81.00^\circ}$	99.92	17.70
500	$1.29/\underline{112.8^\circ}$	$1.2901/\underline{67.19^\circ}$	99.99	45.61
730	$0.891/\underline{124^\circ}$	$0.893/\underline{55.81^\circ}$	99.80	68.19
1,000	$0.65/\underline{138.2^\circ}$	$0.674/\underline{40.10^\circ}$	96.50	98.10
1,750	$0.37/\underline{180^\circ}$	$0.63/\underline{0^\circ}$	58.70	180

Now, in considering the locus of the vector μ, we wish to find the phase angle at which the real part of μ ($\mu\cos\theta$) is a minimum, in order to design our circuits so that the magnitude of the ratio $\mu\angle\theta_1/(1+\mu)\angle\theta_2$ shall never equal or exceed unity. This is assured by making $\mu\cos\theta$, at the frequency of its minimum value, greater than -0.5 as explained in Figure 3.

To find the phase angle at which $\mu\cos\theta$ is a minimum, differentiate $\mu\cos\theta$ as expressed in equation 5 with respect to θ, and solve for μ when $d(\mu\cos\theta)/d\theta=0$.

This gives $\theta=2.16$ radians $=124$ degrees but $f=1.10\theta-1.64$.

Therefore $f=0.73$ megacycles per second which is the frequency at which $\mu\angle\theta_1/(1+\mu)\angle\theta_2$ is a minimum. Since this ratio has been defined previously as E_o/E_{IN} and must be less than unity, we set the ratio equal to 0.998 which is the minimum ratio which we desire through the repeater passband.

Then at 730 kc

$$\frac{\mu\angle 124 \text{ degrees}}{(1+\mu)/\underline{\theta_2}}=0.998$$

which solves for $\mu=0.891$ at 730 kc.

For

$f>10f_2$

$$\mu_{max}=\mu\frac{f}{f_2}=\frac{(0.891)(730)}{f_2} \text{ from equation 3}$$

$$\mu_{max}f_2=650 \qquad (6)$$

μ_{max} has been defined as the absolute value of the forward gain at zero frequency, but at zero frequency the phase shift is also zero. Therefore setting E_o/E_{IN} at zero frequency equal to 0.998 (our minimum ratio)

$$\frac{E_o}{E_{IN}}=\frac{\mu/\underline{0}}{(1+\mu)/\underline{0}}=0.998$$

$$\mu/\underline{0}=499=\mu_{max}$$

Therefore, from equation 6, $f_2=1.3$ kilocycles per second.

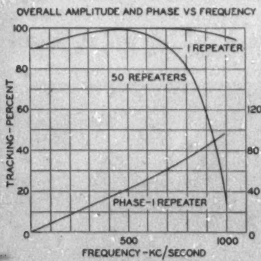

Figure 5. Tracking curves

Having found μ_{max} and f_2 these values can be substituted in equation 3 from which

$$\mu=\mu_{max}\frac{f_2}{f}=\frac{499f_2}{f}=\frac{650}{f}$$

where f is in kilocycles and is greater than $10f_2$.

Or, for all values of f in kilocycles

$$\mu=\frac{\mu_{max}}{\sqrt{1+\left(\frac{f}{f_2}\right)^2}}$$

$$=\frac{499}{\sqrt{1+\left(\frac{f}{1.3}\right)^2}}$$

from equation 3a.

We now have μ and θ, as a function of frequency for our specific design, hence we can now plot $\mu\angle\theta_1/(1+\mu)\angle\theta_2$ as a function of frequency to determine E_o/E_{IN} versus frequency. This is our original measure of performance of the repeater, and the results are shown in Table II and plotted in Figure 5. It is convenient to refer to these results as the "Tracking Coefficient" of the repeater versus frequency.

Figure 5 also includes the response curve of a 50-repeater chain. Variations of the foregoing analysis to obtain different performance curves are possible. For instance, a higher tracking coefficient over the same bandwidth can be obtained by increasing μ_{max} and decreasing f_2; alternately, a lower tracking coefficient can be maintained over the same bandwidth with a smaller μ_{max}.

However, the following summarizing statements will be true:

1. Due to the gain and phase shift characteristics of the system, the feed-back factor is a function of frequency, being highest at low frequencies.

2. The foregoing analysis is accurate only at frequencies where the feedback is adequate to reduce the carrier deviation in the intermediate-frequency amplifier so that the amplitude-modulation analysis of intermediate-frequency amplifier envelope delay does not introduce too large an error.

Considerations in the Design of Electrical Circuitry

The usual receiver design requires a prescribed bandwidth and associated linear phase response. The magnitude of the phase shift is usually not important. However, in this feed-back system, as in any other, the frequency should be as high as possible before the phase shift reaches 180 degrees. To obtain the necessary feed-back factor, a large gain also is necessary. The basic requirement, therefore, is that the ratio of gain to phase shift must be a maximum. A first detector-video amplifier-type of repeater is attractive in principle since a low-pass video-frequency amplifier has a single sided response, thus requiring only one-half the bandwidth of that of a band pass amplifier stage passing the same intelligence. This means that the gain per stage of a video amplifier would be double that of an intermediate-frequency amplifier for the same phase shift. However, the practical difficulties encountered in such a low level video amplifier makes it unfeasible, and various band-pass intermediate-frequency circuits must be considered.

The simplest type is the synchronous single-tuned type. For a given required gain the total time delay should be a minimum. This can be calculated by differentiating $n \tan\theta$ with respect to the variable Q and setting it equal to zero to obtain the minimum.

n = number of stages
θ = phase shift per stage
Q = Q for the resonant circuit

The optimum gain per stage is $\epsilon=2.73$. This result is independent of the intermediate frequency and the type of tubes used although a tube with a high figure of merit should be used to minimize the phase shift for the optimum gain per stage.

The synchronous, double-tuned intermediate-frequency amplifier was investigated next and found superior to the single tuned amplifier. For a given pole configuration, the unsymmetrically damped transformer gives the greatest gain per stage. As the coupling is increased beyond critical coupling, the gain at center frequency decreases slowly but the phase shift also decreases. The net result is that the ratio of gain to phase shift increases with coupling for a multistage amplifier. There is of course a limit to the degree of coupling that can be used. For the overcoupled case, tremendous peaks occur outside the desired passband thus increasing the noise bandwidth and reducing the selectivity of the amplifier. In our calculation, critically coupled circuits were used.

Rejection of amplitude modulation of the incoming carrier may be obtained by means of a conventional limiter following the intermediate-frequency amplifier, although such circuits have poor gain, phase shift characteristics, and a fast automatic gain control circuit appears to be more advantageous.

The conventional Foster-Seeley discriminator was chosen in our experiments for its sensitivity and bandwidth capabilities. The narrow-band video-amplifier stage can conveniently be made to have very high gain by supplying it with an adequate plate supply voltage, so that although it may have 90 degrees of phase shift throughout most of the useful band its gain to phase shift ratio is favorable. Further, it is often convenient to direct couple through all video circuits from the discriminator output to the radio-frequency oscillator control electrode. By this means automatic frequency control, whereby the oscillator is locked on the incoming carrier but differing therefrom by the intermediate-frequency center frequency, can be obtained with conventional circuitry, see Figure 6.

In most applications it will usually be found desirable to include some radio frequency preselection ahead of the first detector. This may take the form of a waveguide filter. Since it is outside of the feed-back loop, it does not affect the feed-back calculations and it must be treated as a parameter in the external transmission circuit.

Mechanical Considerations

In the application of any repeater, the mechanical properties may be as important as other characteristics. In one design, a parabolic antenna, employing a waveguide horn feed, was equipped on the rear with an insulated aluminum box measuring 14 by 12 by 8 inches. The entire assembly was designed for sealing and pressurization and, ready for mounting, would weigh under 50 pounds. Figure 7 is a typical waveguide assembly including the radio-frequency oscillator tube and mount, output transmission line, crystal mixer mount, and a triple tuned waveguide input preselector. The amplifier stages have been assembled on a 6 by 8 inch chassis which is mounted from the waveguide. This assembly did not include any provision for mounting a second or transmitting antenna, as this requirement would vary with installations.

It would not appear that this repeater would ordinarily be mounted on a tower since its size would permit satisfactory mounting from an "I" beam or pole. Similarly no power supplies are included in the basic design since the 35-watt total power requirement of the repeater may be obtained in many ways.

System Specifications

This paper cannot dwell at length on the specifications of a complete repeater system but a few highlights should be emphasized. First, the feed-back ratio of the repeater in our example is 54 decibels at zero frequency, and the ratio decreases from 51 decibels at 1.3 kc, at the rate of 6 decibels per octave, to a value of 3 decibels at 330 kc. Thus if the harmonic distortion of the repeater is at the level of −35 decibels below signal without feedback, the repeater with feedback could be expected to be improved by the above feed-back ratios. Also a considerable reduction in microphonic or other disturbances occurring within the feed-back loop can be expected.

A typical signal to noise calculation for a repeater operating with a transmitter power of 50 milliwatts might be as shown in Table III.

Table III

	Decibels
Transmitter power (50 milliwatts)	−10
Antennas gain (two 4-foot parabolic antennas at 6,500 megacycles)	+74
Transmission loss (25 miles)	−138
Converter and input circuit noise figure	−14
Receiver noise level (±7 megacycles bandwidth)	−133
Frequency modulation improvement (±3 megacycles deviation with 0.5 megacycles video bandwidth)	+20
Video signal/noise ratio	65

Conclusions

The radio repeater system described in this paper appears from calculations and tests to have many desirable characteristics when applied to the problem of relaying communication signals of medium bandwidth over long relay chains. The application of negative feedback ap-

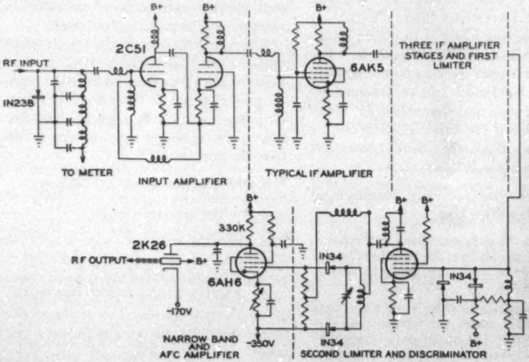

Figure 6 (left). Partial schematic diagram

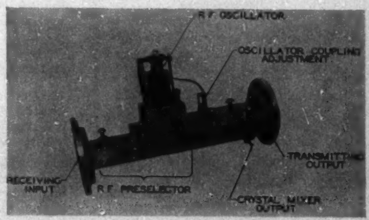
Figure 7 (below). Repeater waveguide assembly



pears to have materially improved the performance of the remodulation type of repeater and thereby increased its application range and usefulness. Many avenues of improvement over the repeater described are still open for investigation, but the existing design represents the summation of our initial work.

A New Expanded Scale A-C Voltmeter

N. P. MILLAR
ASSOCIATE AIEE

THE accurate measurement of power system voltage has become increasingly more important to the power station attendant than in former years. There are several reasons why this is true as the complexity of system operation has increased with the growth of household, commercial, and industrial power demands. A few of the more important reasons for voltage measurement are:

1. To facilitate interconnections between systems. All stations participating in interconnection activities must have their voltages set to within reasonable limits of each other.
2. To satisfy more critical home appliance voltage requirements, particularly for electric stoves and other heating devices.
3. To control central station bus voltages in order to keep operations within the capacity ratings of generating and distribution equipment.

Method Used for Scale Expansion

Heretofore, the measurement of voltage has been accomplished by conventional zero-left a-c moving-iron or electrodynamic voltmeters with square law scale distribution characteristics. Experience has shown that in many applications the measurement problem consists of detecting and measuring a variation of ±1 volt or less from a given reference voltage. This reference voltage is usually 120 volts or multiple thereof as determined by potential transformers. A 1-volt variation from 120 volts represents approximately $^3/_{64}$ inches of arc on a standard 250 degree scale concentric-type switchboard voltmeter, or approximately $^1/_{32}$ inches for conventional 6-inch rectangular voltmeters with 90 degrees scales. Frequently this is not enough of a deflection to read with the desired degree of certainty, since the smallest division on the 250 degree scale corresponds to two volts, and the 1-volt position has to be estimated while in the 90 degree scale instrument the smallest division is usually five volts.

Any instrument that is offered as a solution to this problem must have as a general objective a scale expansion characteristic within the range of the normal voltage variation that produces a scale length per volt of approximately four times that of the standard voltmeter. This gives a scale arc of approximately $^3/_{16}$ inches per volt for the 250 degree scale-type instrument only.

Two general engineering approaches that have been employed in the development of expanded scale voltmeters are:

1. A modification of the basic instrument mechanism.
2. The use of standard mechanisms with impedance networks, the outputs of which vary as some function of the voltage to be measured.

Modified Instrument Mechanisms

One of the simplest methods of modifying the basic instrument mechanism is to suppress the natural zero position of a standard a-c voltmeter. In an ordinary voltmeter, the normal unenergized position of the pointer is at the left end of the scale. Suppression of this zero is accomplished by shifting the position of the control spring on the pointer shaft in a direction to cause the zero to be located at a point beyond the left end of the scale. When this is done, the pointer is restrained by a stop at this end of the scale and will not deflect until an appreciable voltage is applied. A certain degree of scale expansion can be realized by this method, but there is a limit to the amount the zero position can be suppressed. As this amount is increased to give greater scale expansion, the instrument finally becomes unstable. Figure 1 shows by a plot of the dynamic and control spring torque curves the scale distribution that results before and after the zero has been suppressed. Near the point of instability, the torque gradient is nearly zero and the instrument behaves in a sluggish manner. Action of the pointer gives the impression of excessive jewel roll as indicated by gently tapping the instrument. When the instrument responds in this manner, the indicated measurement becomes unreliable. In general for 90 degree scale voltmeters of the moving-iron and electrodynamic types, the zero can be suppressed only 30 to 40 angular degrees.

An equally serious objection to the suppressed zero instrument is the loss of the natural zero setting. Since it is no longer possible to check visually the natural position of the pointer with the instrument unenergized, frequent checks of accuracy with a carefully controlled voltage reference are necessary to determine the constancy of the initial calibration.

Impedance Networks

There are numerous types of expanded scale voltmeters which function in response to the variation of an impedance in some kind of a network to produce an

expanded scale distribution. These may have: (a) auxiliary means to produce a voltage that bucks down a portion of the measured voltage; (b) some sort of an electronic tube circuit that cuts out all but the desired voltage range and rectifies the output to be indicated on a conventional permanent-magnet moving-coil end device; or (c) nonlinear circuit parameters in suitable networks.

The most serious problem that confronts an engineer who chooses to develop an expanded scale voltmeter utilizing the afore-mentioned methods is one of component stability. Moreover, for the methods of types (a) and (b), power must be used which further complicates the design and application of the voltmeter.

Saturable Reactor Networks

The most practical solution to the problem of scale expansion is the use of an iron-core saturable reactor in combination with an instrument of the electrodynamic type. Of all the known types of nonlinear circuit components, the iron-core reactor gives the most stable and reproducible performance characteristics. If a voltage is applied across such a reactor, the exciting current will vary in a nonlinear fashion with the voltage. Any suitable a-c milliammeter connected in series with this reactor to measure the exciting current could have its scale calibrated in terms of volts. The scale distribution then would correspond to the nonlinear variation of the exciting current. The milliammeter, therefore, becomes an expanded scale voltmeter that has a good torque gradient and a natural zero position on the scale.

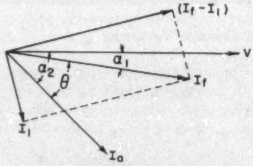

Figure 3. Vector diagram of expanded scale voltmeter

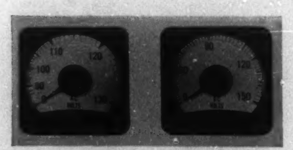

Figure 4. General Electric switchboard long-scale a-c voltmeters

Expanded scale (left) and standard scale (right)

Theoretically, an expanded scale voltmeter could be made using an a-c milliammeter as described, but the application would be impractical for two reasons: the volt-ampere burden would be excessive as compared to normal a-c voltmeter burdens; and the system would not lend itself to convenient and effective frequency compensation, which, it will be recognized, is necessary if a reactor is to be used. These objections can be overcome by placing the saturable reactor in series with the moving coil of a standard electrodynamic wattmeter mechanism and making connections to the voltage source as shown in the schematic diagram of Figure 2. It will be noticed that both the field and moving-coil circuits of the wattmeter are connected in parallel. Frequency compensation can be applied easily by placing a resistance-capacitance network in the field circuit and making the impedance predominantly capacitative. Corrective frequency action can be visualized to advantage by referring to a typical vector diagram of this application as shown in Figure 3.

As frequency increases, the magnitude of the moving-coil current I_a decreases and its phase angle α_2 increases. However, since the field circuit impedance is capacitative, the magnitude of the field current I_f and its phase angle α_1 varies in such a manner as to offset the effect of the armature current change. This results in the instrument torque remaining constant over a reasonable range of frequency variation. With the reactor placed in the moving-coil circuit where the current is small for wattmeter operation, the resulting total volt-ampere burden is comparable with that of the standard voltmeter.

This principle of scale expansion has been applied to an actual design which meets the general requirements of scale expansion without the instability characteristics of other methods.

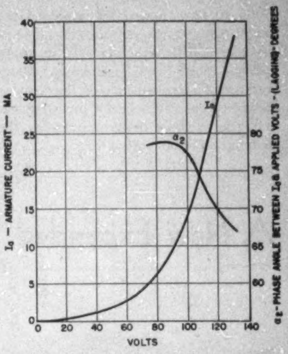

Figure 5. Variation of moving-coil current and phase angle with voltage—expanded scale voltmeter

Design and Performance of Saturable Reactor Voltmeter

The general appearance and design of an a-c expanded scale voltmeter that depends for its scale expansion on the nonlinear characteristics of a reactor follows the same pattern as that of the long-scale indicating instruments described elsewhere.[1,2] It maintains a 250 degree scale arc and utilizes approximately 220 degrees of that arc in expansion from 90 to 130 volts, where 0 to 130 volts is the volt-

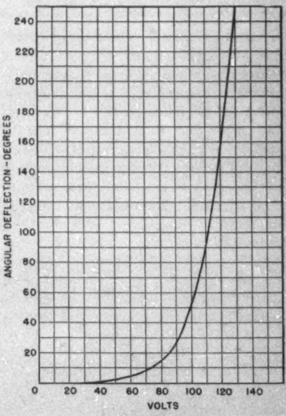

Figure 6. Voltage-deflection curve of expanded scale voltmeter

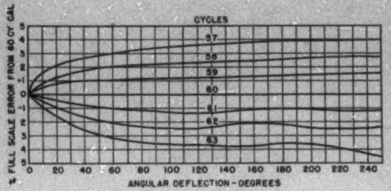

Figure 7. (left) Uncompensated frequency error of expanded scale voltmeter

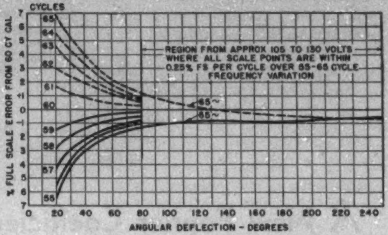

Figure 8. (right) Compensated frequency error of expanded scale voltmeter

meter rating. Figure 4 shows the actual scale distribution of this new device and, for comparison, the distribution of a normal 150-volt voltmeter also is shown.

The average torque on the moving-coil shaft can be written the same as that for any standard electrodynamic system, that is

$$T_{av} = kI_fI_a \cos \alpha$$

where

I_f = field current, amperes, rms
I_a = moving-coil current, amperes, rms
α = phase angle between I_f and I_a, degrees
k = constant of proportionality

In this application, however, current I_a is a nonlinear quantity that varies with voltage approximately as shown in Figure 5. Also shown is the moving-coil current phase angle α_1 as it decreases with increasing voltage. From the generalized circuit diagram, Figure 2, it will be noted that, as the applied voltage increases, the field current I_f also increases, thus aiding the expansion characteristic of the moving-coil current. Altogether, the combined effect produces a rather steep voltage-deflection curve or scale distribution as shown in Figure 6. One half-volt variations can be detected and read easily in the expanded region from 90 to 130 volts with an accuracy of $^1/_2$ per cent of full scale.

The theoretical method of frequency compensation was described in detail in the preceding section on the application of the saturating reactor to a generalized instrument. In practice it is possible to compensate the expanded scale voltmeter so that its frequency error is within ±1/4 per cent of full scale per cycle from 105 to 130 volts and over a ±5-cycle variation from a reference frequency of 60 cycles. Figures 7 and 8 show the frequency error of the expanded scale voltmeter before and after compensation respectively.

This device has a wave form error of less than one per cent of full scale when the voltage source contains both third and fifth harmonics of 5 per cent each. This distortion represents a maximum condition that may be encountered in a large number of power systems, and the average third and fifth harmonic voltages are in the order of 1 to 1.2 per cent of normal.

The average ambient temperature error is shown in Figure 9 in curve form. The temperature coefficient is plus 0.021 per cent per degree centigrade rise from plus 15 to plus 55 degrees centigrade.

The total volt-ampere burden of the voltmeter is nonlinear with the applied voltage as might be expected, and varies from 2.6 at 90 volts to 7.4 at 130 volts full scale, see Figure 10.

Table I lists the important physical constants of the expanded-scale a-c voltmeter in comparison of those of the standard 0-to-150-volt long-scale types.

Table I. Comparative Physical Constants

	Expanded Scale Voltmeter		Standard Voltmeter
Type	AB15	...	AB15
Rating, volts	130	...	150
Accuracy, per cent full scale	0.5	...	1.0
Scale length, inches	7.1	...	7.1
Expansion range, volts	90–130	...	none
Full scale torque, gram-millimeters	7.23	...	4.20
Full scale torque, weight	2.82	...	1.36
Damping factor	67/infinity	...	17.7/infinity
Response time, seconds	0.85	...	1.3

Conclusion

The successful application of a saturating core reactor to a standard electrodynamic wattmeter mechanism has resulted in an expanded scale a-c voltmeter with improved accuracy and reliability. The device is self-contained and requires no auxiliary means for operation. A natural zero has been maintained, and the moving-coil system operates with a high torque gradient for all scale points in the expanded region. A fast-responding moving system makes the device sensitive to small and rapid voltage fluctuations.

It is possible to apply this method of scale expansion to recording instruments and thereby obtain a permanent record of actual voltage fluctuations about a given reference. Since the device is extremely sensitive in the expanded region, the possibility also is suggested for using the principle to advantage in precise voltage control applications.

A New Fourier Coefficient Harmonic Analyzer

S. CHARP
MEMBER AIEE

THE Fourier-coefficient harmonic analyzer is a machine designed primarily for evaluating the Fourier coefficients of periodic waves, or sections of complex waves which are assumed to be periodic outside of the interval within which the wave is to be analyzed. Its usefulness is not limited to any particular branch of engineering or to a particular branch of mathematics, and its general utility and application in the solution of a wide variety of problems ranging in scope from communications to medicine will be evident.

Harmonic analyzers have been constructed in the past, but for the most part they have been large and bulky and far more limited as to the number of harmonics for which a wave can be analyzed than the machine described in this paper. Typical of the large and bulky machines are those which accept as inputs the amplitudes of the sine and cosine components of a wave and produce, usually in the form of a curve, a composite trace of the harmonic components.[1,2] These machines can be used to a limited extent for harmonic analysis, but the range of harmonics which can be obtained is rather restricted. Only two harmonic analyzers have come to the attention of the author which in any way approximate this new machine as to physical size, but neither of them has the harmonic range, the ease of operation, nor the mechanical design features which are incorporated in the machine described.[3,4]

General Description of Machine

The Fourier-coefficient harmonic analyzer can be considered to be a small special-purpose differential analyzer, permanently set up to solve for the Fourier coefficients. It consists essentially of a number of ball-and-roller-type (Ford) integrators and interconnecting mechanisms and counters. Figure 1 is an overall view of the analyzer; Figure 2 shows the front view of the machine proper. The active components are mounted on an aluminum framework provided with free-rolling casters, allowing ready moving of the machine from place to place.

This analyzer carries out the integrations of the following equations which define the coefficients of the Fourier series

$$F(\theta)=A_0/2+\sum_{1}^{\infty}A_n\cos n\theta+\sum_{1}^{\infty}B_n\sin n\theta \quad (1A)$$

$$A_0=\frac{1}{\pi}\int_0^{2\pi}F(\theta)d\theta \quad (1B)$$

$$A_n=\frac{1}{\pi}\int_0^{2\pi}F(\theta)\cos n\theta d\theta \quad (2)$$

$$B_n=\frac{1}{\pi}\int_0^{2\pi}F(\theta)\sin n\theta d\theta \quad (3)$$

Use is made of some of the techniques peculiar to the operation of a mechanical integrator. In such a device, the integrand moves proportionally to the ordinate of the given curve, $F(\theta)$, to be analyzed, and the disk rotates in proportion to the independent variable θ. The incremental output, dA_0, of the integrator is proportional to the product of the two inputs, that is

$$dA_0\propto F(\theta)d\theta \quad (4)$$

Now, the right-hand side of this expression is included in the integrals defining A_n and B_n, hence, upon substitution, these latter coefficients assume the form, neglecting scale and proportionality factors

$$A_0=\frac{1}{\pi}\int_0^{2\pi}F(\theta)d\theta \quad (5)$$

$$A_n=\frac{1}{\pi}\int_{\theta=0}^{\theta=2\pi}\cos n\theta dA_0 \quad (6)$$

$$B_n=\frac{1}{\pi}\int_{=0}^{\theta=2\pi}\sin n\theta dA_0 \quad (7)$$

The implication of these equations is that if one integrator can be made to produce the term A_0 as an output-shaft rotation, then this quantity can be fed into other integrators as a differential input. The outputs of these latter integrators, when the integration is performed over the

Figure 1. Over-all view of the harmonic analyzer

Paper 49-163, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer General Meeting, Swampscott, Mass., June 20–24, 1949. Manuscript submitted August 11, 1948; made available for printing April 29, 1949.

S. Charp is Research Engineer at The Franklin Institute Laboratories for Research and Development, Philadelphia, Pa. The harmonic analyzer was developed while he was Research Associate in Electrical Engineering at the Moore School of Electrical Engineering, University of Pennsylvania, Philadelphia, Pa.

The author wishes to acknowledge the helpful suggestions of Dr. C. N. Weygandt and M. E. Nelson, and the valuable design efforts of M. Unis and J. P. Moore, all members of the Moore School staff.

Figure 2. Front view of the harmonic analyzer

proper interval, are the coefficients A_n and B_n. The use of integrators in this cascaded scheme differentiates this harmonic analyzer from the Henrici-Coradi analyzer, from the point of view of how the computations for the coefficients are mathematically carried out.

It is further to be noted that the coefficients A_0, A_n, and B_n are so defined only after the integration is carried out over one period of the independent variable, in this case the angular distance 2π radians.

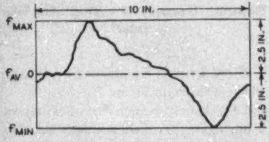

Figure 3. Plotted curve as used on harmonic analyzer

Stated in another way, the coefficients A_n and B_n can be written as

$$A_n=\frac{1}{\pi}\int_{\theta=0}^{\theta=2\pi}\cos n\theta d[\int F(\theta)d\theta] \tag{8}$$

$$B_n=\frac{1}{\pi}\int_{\theta=0}^{\theta=2\pi}\sin n\theta d[\int F(\theta)d\theta] \tag{9}$$

which is the form used in this harmonic analyzer.

Referring back to equation 1(A), it is seen that terms of like frequency appear as sines and cosines. These can be combined to obtain the magnitude and phase of each harmonic relative to the component of fundamental frequency. The final form of the Fourier series becomes

$$\begin{aligned}F(\theta)=A_0/2+C_1\cos(\theta-\phi_1)+\\ C_2\cos(2\theta-\phi_2)+\ldots.+\\ C_n\cos(n\theta-\phi_n)+\ldots\end{aligned} \tag{10}$$

$$F(\theta)=A_0/2+\sum_{n=1}^{\infty}C_n\cos(n\theta-\phi_n) \tag{11}$$

where

$$C_n=[A_n^2+B_n^2]^{1/2} \tag{12}$$

$$\phi_n=\tan^{-1}(B_n/A_n) \tag{13}$$

By applying equations 12 and 13, the magnitude and phase can be determined for each of the harmonics present in the given curve.

The preparation of a curve to be analyzed on this machine is straight-forward, the chief requirement being that the peak-to-peak excursion of the ordinate must be less than or equal to five inches, this size being most desirable from the point of view of maximum utilization of the integrator and hence for maximum accuracy. From the physical or experimental data from which the curve is to be plotted, one can determine the absolute maximum value of the function, f_{max}, and the absolute minimum, f_{min}. The average value, f_{avg}, is computed as the arithmetic mean value of the peak-to-peak values of the function

$$f_{avg}=\frac{f_{max}+f_{min}}{2} \tag{14}$$

The conversion factor for changing the physical measured data to inches displacement along the plotted curve is given by

$$K=\frac{5}{[f_{max}-f_{min}]} \tag{15}$$

and, in terms of inch displacement, the curve to be analyzed can be expressed as

$$f_{inches}=[f-f_{avg}]\times\frac{5}{[f_{max}-f_{min}]} \tag{16}$$

This last equation represents the displacement of the ordinate from the f_{avg} line as a fiducial zero.

If the curve to be analyzed has a peak-to-peak displacement of less than five inches, then substitute this value for the number *5* in equations 15 and 16.

The abscissa likewise has to be scaled, in this case to a 10-inch length. This distance represents period of the fundamental of the function to be analyzed, and corresponds to an angular measure of 2π radians.

Figure 3 shows the finished form of a plotted curve ready for analysis.

Block Diagram and Functional Layout

Of the four ball-and-roller integrators used in this machine, three are used to perform the integration process, and one is used as a variable speed drive, in discrete steps, obviating the use of change gears.

Figures 4 and 5 are over-all top views of the analyzer from the front and rear re-

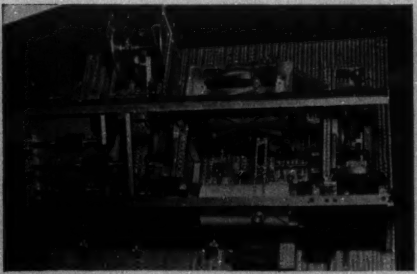

Figure 4. Top front view of the analyzer with plastic cover removed

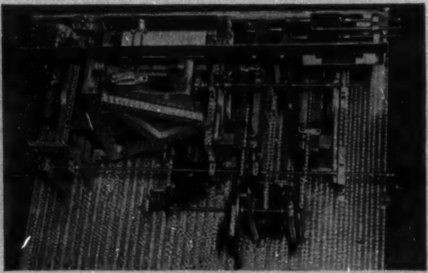

Figure 5. Top rear view of the analyzer with plastic cover removed

spectively, showing the integrator layout as well as the major components.

A functional block diagram of the analyzer is shown in Figure 6, the symbols used being those common in differential analyzer work. It is to be noted that no gear changes are required; the analyzer is totally self-contained. Scale factors chosen for the integrators are such as to use them to their fullest designed capacity.

At this point, a detailed account of the operation performed by each integrator is appropriate.

The 5-inch integrator is designed with an integrator constant equal to 8/3; that is, the integrator equation is $y=(8/3)\int R\,dx$, where y is the number of revolutions of the output shaft, R is the displacement of the balls off center in inches, and x is the number of revolutions of the integrator disk. In this analyzer, each integrator disk is driven through a gear ratio of 1-to-5; hence, the integrator constant is taken as 8/15, or $y=(8/15)\int R\,dx$.

INTEGRATOR I

Integrator I solves for the constant term A_0. It accepts as one input, to drive the ball carriage, information proportional to the instantaneous ordinate of the curve. The integrator disk, coupled to the drive motor, rotates an amount proportional to the variable of integration. Referring to Figure 6, it is seen that the output of the first integrator is given by

$$\frac{8}{15}\int_0^{2\pi} f_{inch}\, d\left[\frac{450\theta}{2\pi}\right]=\frac{8}{15}\times \frac{450}{2\pi}K\left[\int_0^{2\pi}F(\theta)d\theta-\int_0^{2\pi}f_{avg}\,d\theta\right] \quad (17)$$

$$\text{Output turns}=120KA_0-240Kf_{avg} \quad (18)$$

After passing through a fixed-gear-ratio chain drive, 48-to-10, the A_0 counter reads

$$576KA_0-1152Kf_{avg} \quad (19)$$

The constant term then becomes

$$A_0=\frac{\text{Counter Reading}}{576K}+2f_{avg} \quad (20)$$

INTEGRATOR II

The differential or integrator disk of Integrator II is driven directly by the output of Integrator I, while the integrand is moved by the Scotch yoke as a cosine function, with a maximum amplitude of $2^1/_2$ inches. The output roller then turns as

$$\frac{8}{15}\int_{\theta=0}^{\theta=2\pi} 2.5\cos n\theta d[120KA_0]=160KA_n \quad (21)$$

This rotation passes through a fixed-gear-ratio chain drive, 36-to-10, so that the A_n counter reads 576 K A_n. The amplitude of the *nth*-harmonic cosine wave is given by

$$A_n=\text{Counter Reading}/576K \quad (22)$$

INTEGRATOR III

In a similar manner it can be shown that Integrator III produces the amplitude of the *nth*-harmonic sine wave, given by

$$B_n=\text{Counter Reading}/576K \quad (23)$$

INTEGRATOR IV

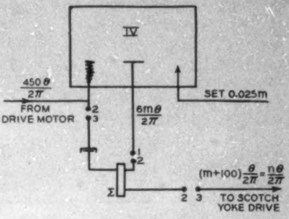

Figure 7. Method of production of the *nth* harmonic

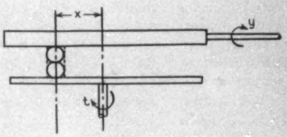

Figure 8. Geometry of ball-and-roller integrator

The fourth integrator is used as a variable-ratio device to produce a shaft rotation n times that of the fundamental. The entire range of harmonics from 1 to 100 is produced; the most accurate region of the integrator is utilized by means of a clutch by-pass circuit, a schematic of which is shown in Figure 7.

A calibrated precision lead screw having a pitch of 0.025 inch positions the carriage. The letter m, used in Figure 7, represents the complement of the harmonic number with respect to 100 with sign reversed; that is, the number of the harmonic, n, equals $100+m$, or $n=100+m$. Therefore, for the first harmonic, $n=1$ and $m=-99$. The output of the integrator is fed into one side of a mechanical adder device, the other side of which is fed through a clutch mechanism from the drive motor producing the independent variable. The output of the adder, after gear reduction, produces a shaft rotation just n times that of the fundamental. For harmonic settings less than 50, the clutch is engaged; the m settings are negative, in range from −99 to −50, producing harmonics from 1 to 50. Notice that the carriage setting is from −2.475

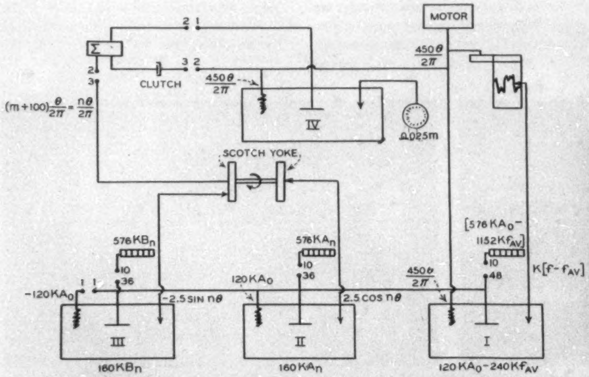

Figure 6. Block diagram of harmonic analyzer interconnections

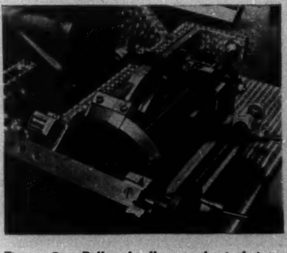

Figure 9. Ball-and-roller mechanical integrator partially opened

to −1.250 inches. For harmonics greater than 50, the clutch mechanism is disengaged; the m numbers are varied from 50 to 100, over the positive part of the integrator disk, that is, the carriage displacement is from 1.250 inches to 2.500 inches. The central part of the disk is not used. The by-pass adder circuit just described can be seen located between the Scotch yokes in Figures 4, 5, and 11.

Description of Major Components

DOUBLE-BALL INTEGRATOR

The most essential single mechanism of the harmonic analyzer is the mechanical ball-and-roller integrator,[5] a common component of many gun fire control computers. The mechanism has two input shafts and one output shaft, arranged so that the ratio of the incremental rotation of the output shaft to that of one of the input shafts is proportional to the rotation of the second input shaft

$$\frac{\Delta y}{\Delta t}=kx \tag{24}$$

$$y=k\int_{t_1}^{t} xdt \tag{25}$$

where

y = output shaft rotation
t = input shaft rotation
x = input shaft rotation

Figure 8 shows the geometry of a ball-and-roller integrator. Figure 9 is a photograph of integrator IV used in the machine, opened up to show construction details. The rotating integrator disk is used as one input, supplying the differential of equation 25. Two steel balls, one on top of the other, are held in position in a carriage which moves across the disk on a pair of guide rails. The position of this carriage with respect to the center of the disk, denoted by x in Figure 8, represents the integrand of equation 25. When the disk rotates about its center, and the carriage carrying the balls is displaced off the center of the disk, the motion of the bottom ball is transmitted to the roller shaft or output roller, yielding the value of the integral, equation 25, as a continuous function. This type of integrator is similar to the wheel-and-disk integrators used so extensively in the large multipurpose differential analyzers built in this country.[6]

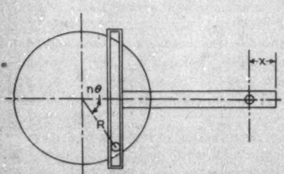

Figure 10. Geometry of Scotch-yoke mechanism

The mechanical integrator, performing a process of continuous addition, has no knowledge of the physical nature of the driving functions; that is, the x and t of equation 25 can be any functions whatsoever and the output will still be given, in functional form, by equation 25. In the particular case of the harmonic analyzer, the integrand is a sinusoid. Cosine $n\theta$ of equation 6 corresponds to the x of equation 25, and the differential dt in Equation 25 is represented by the function $d\,A_0$ of equation 6. Equation 25 then can be written in place of Equation 6, with the integration between the limits corresponding to $0 \leq \theta \leq 2\pi$.

SINE AND COSINE GENERATORS

The sine and cosine functions necessary for the integrations are generated by a finely-machined Scotch-yoke mechanism, similar to that shown in Figures 10 and 11. An aluminum disk has imbedded in it a hardened steel pin at a distance R from the center, equal to the amplitude of the sinusoid to be generated. This pin moves between two rails in a framework constrained to move along one axis only. Upon rotation of the disk the T-arm will move in translation, and the instantaneous displacement will be a true sinusoid, equal to $R \cos n\theta$, with zero theoretical error. It is most important that this mechanism be precisely built, since even a small amount of play or backlash between the steel pin and the guide rails may seriously impair the accuracy of the analyzer output.

Figure 11. Scotch-yoke mechanism showing adder by-pass circuit

Two Scotch-yoke mechanisms are utilized in the harmonic analyzer, one to produce the sine, the other the cosine, as shown in Figure 11. The two yokes are mounted on a common center, the pins being displaced exactly 90 degrees apart; hence, one unit generates the sine, the other the cosine, both at the same frequency. The integrals, given by equations 6 and 7, require the use of multiple-frequency sinusoids, that is, cos $n\theta$ and sin $n\theta$. The effect of a frequency higher than the fundamental is obtained by rotating the Scotch-yoke disk at a correspondingly higher speed than is used in scanning the curve under analysis. For example, if the base speed of rotation of the disk is that which obtains when the fundamental frequency is being generated, then the second harmonic is obtained by rotating the disk at twice base speed, the third harmonic by rotating at three times base speed, and so forth. The exact method of setting the frequency is outlined below.

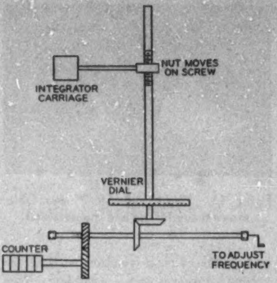

Figure 12. Details of the harmonic-setting mechanism

FREQUENCY-SETTING INTEGRATOR

A 5-inch ball-and-roller integrator is used as a variable gear ratio, whose function is to produce a shaft rotation proportional to the particular harmonic frequency to be investigated. As was noted above, any integrator has an incremental output given by

$$y=k\int_{t_1}^{t} xdt$$

where k is the integrator constant, x is the displacement from center of the integrator carriage carrying the balls, and t is the integrator-disk rotation. Obviously, if $x=c=$ constant, the output of such integrator, not including the initial offset, will be $k\,c\,t=k_1t$, or the output equals the input times the constant k_1. Use is made of this fact by driving the integrator disk with the independent variable θ, and ad-

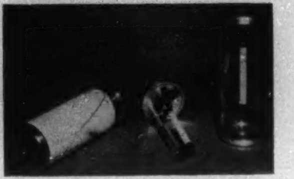

Figure 13. Plastic cylindrical curve table, shown ready for use and disassembled

justing the carriage position so that the output rotation is an *nth* harmonic. This *nth*-harmonic angle is used to drive the Scotch-yoke mechanism through either a direct or indirect path, producing sin $n\theta$ and cos $n\theta$.

Figures 9 and 12 show details of the harmonic-setting mechanism. The integrator carriage is carried along by a nut riding on a precision-ground lead screw having a pitch of 0.025 inch. Thus, each turn of the lead screw moves the carriage away from center by this amount. It will be shown later that each turn of the lead screw, or each advance of 0.025 inch, corresponds to another harmonic. When the frequency setting wheel is turned, during the machine adjustment period and prior to investigating for the presence of a harmonic in the given curve, the integrator carriage is displaced, and the counter, shown in Figures 9 and 12, indicates the distance of the carriage off center, to the nearest 0.001 inch. The vernier dial is graduated into 250 divisions; hence, each division represents a displacement of 0.0001 inch. It is thus theoretically possible to set the carriage to within ±0.00005 inch, but, because of certain inherent play and backlash in the ball carriage and the fact that the balls do not have a precise point contact, the actual precision of setting is not as accurate. A calibration chart is provided to relate the number of the harmonic to be investigated and the setting of the carriage.

INPUT TABLE

The curve whose harmonic content is to be investigated is plotted on a piece of paper to a standard size, 5 by 10 inches, the smaller dimension representing the maximum peak-to-peak excursion of the function, and the larger size representing the independent-variable scale. Linear graph paper having twenty lines to the inch, $7^1/_2$ by 10 inches ruled spacing with margin, has been found to be quite suitable.

The curve is wrapped around a plastic cylinder, shown in Figure 13, and inserted in the machine. This cylinder is shown in position in Figure 2. When the analyzer is in operation, the cylinder rotates an amount proportional to the independent variable, 0 to 2π radians, and the operator tracks the curve by sighting through an eyepiece and turning the tracking hand wheel located on the front panel. This latter motion is then transmitted to the integrator, which computes the constant term A_0 in the Fourier series.

Some thought was given to providing automatic curve following rather than hand tracking, and such feature may be incorporated into the machine at a later date. The use of an automatic curve follower would materially reduce the time to make an analysis, possibly by a factor of three.

The input cylinder assembly, shown in Figure 13, consists of the plastic cylinder proper, two aluminum end pieces, and a fluorescent light mounted within, with brush contacts brought out at one end. During operation, this internal light provides illumination behind the curve sheet.

The eyepiece is provided with a pair of adjusting screws which allows it to be displaced laterally over a distance of about 0.15 inch. This is most desirable, especially when adjusting for the zero line of the curve and the integrator.

OUTPUT COUNTERS

The results of the integrations of equations 5, 6, and 7 appear on counters located at the front upper-left-hand part of the analyzer. Except for a multiplying scale factor, these counters yield directly the magnitudes of the constant term and the sine and cosine amplitudes for each frequency investigated. Combination of the coefficients according to equations 11, 12, and 13 yield a resultant magnitude and phase relative to the fundamental. The counters are shown in Figures 2 and 4; they can be read to about 0.02 revolution.

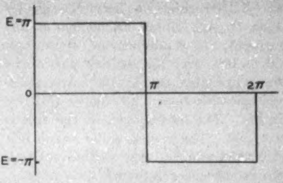

Figure 14. Square-wave used for checking purposes

Example of Square-Wave Analysis

The square wave, shown in Figure 14, was used to check the inherent accuracy of the harmonic analyzer. This is a particularly useful curve in this respect, because no tracking error is involved, except for an initial setting by eye of the tracking eyepiece.

Initial setting was by eye rather than by precise measurement in order to approximate the human setting error. The wave shown in Figure 14 can

True A_0 and true A_n are both zero throughout (See text).

*Actual computed B_n was greater than this figure by 0.0055. This error is attributed to nonaccurate zero setting, hence this constant amount was subtracted from each entry.

be formally expanded in a Fourier series as follows

$$F(\theta)=\frac{4E}{\pi}\sum_{n=1,3,5\ldots}^{\infty}\frac{1}{n}\sin n\theta \qquad (26)$$

For the case of $E=\pi$, the series becomes

$$F(\theta)=4\sum_{n=1,3,5,\ldots}^{\infty}\frac{1}{n}\sin n\theta \qquad (27)$$

The constants necessary for the analysis are now determined as follows

$$f_{max}=\pi \qquad (28)$$

$$f_{min}=-\pi \qquad (29)$$

$$f_{avg}=(\pi-\pi)/2=0 \qquad (30)$$

$$K=5/2\pi=2.5/\pi \qquad (31)$$

$$f_{inches}=(2.5/\pi)F \qquad (32)$$

This latter equation allows the plotting of the curve from the original data. The integrated constants are as follows

$$\begin{aligned}A_0=A_n=B_n&=\text{Counter reading}/576K\\&=(\pi/1440)\times\text{Counter reading}\\&=0.0021816\times\text{Counter reading} \qquad (33)\end{aligned}$$

Table I shows the true and the computed values of the amplitudes of some of the harmonics in the square wave. The analyzer always computes all coefficients, A_0, A_n, and B_n. When only sine terms are theoretically present in a curve, and A_0 and A_n do not vanish, then their presence may give rise to an error in addition to any error in the computed amplitude of the sine curve.

From Table I, it is seen that the square wave analyzed produced coefficients for terms which are not theoretically present in this kind of wave. It is felt that these spurious coefficients are due almost entirely to tracking. In some cases, there is no appreciable error introduced by these terms. Consider, for example, the ninth harmonic, having $A_9=-0.0061$ and $B_9=0.4455$. The theoretical value of $B_9=0.4444$, and on the basis of the B_9 terms only, there is an error in the amplitude of this coefficient of 0.25 per cent. If the A_9 term is taken into account, the amplitude of the sinusoid remains the same to four significant figures, with the same accuracy as if this term were not present.

Only odd harmonics are present in the odd-function square wave, but the analyzer gave results of a rather constant but very small magnitude for the even harmonics; their contribution to the error was small.

The error inherent in the harmonic analyzer can be measured either with respect to the theoretically true value of the amplitude of the harmonic, or with respect to the contribution which this error makes to the over-all curve. It is an easy matter to measure the former, as is shown in Table I. As can be seen, even if the error in the amplitude of harmonic *49* is 0.86 per cent, the true amplitude of this harmonic still is only 2.04 per cent of the fundamental, and the net effect of the curve which would be synthetized from the Fourier series would be quite small.

Appendix I. Theoretical Error Due to Missetting of Frequency

The coefficients of the Fourier series are given exactly by the integrals

$$A_0=\frac{1}{\pi}\int_0^{2\pi}F(\theta)d\theta \qquad (1B)$$

$$A_n=\frac{1}{\pi}\int_0^{2\pi}F(\theta)\cos n\theta d\theta \qquad (2)$$

$$B_n=\frac{1}{\pi}\int_0^{2\pi}F(\theta)\sin n\theta d\theta \qquad (3)$$

only when the harmonic number n is, of course, an integer, and when the integration is carried out over exactly one period, $\theta=2\pi$. In this harmonic analyzer, the period of integration is determined by the curve sheet, that is, the distance along the independent variable axis, from beginning to end, is 2π, regardless of any setting of the harmonic. It is desirable, however, to investigate the error in the A_n or B_n counter reading representing the amplitude of a harmonic, when the frequency setting is a non-integer, that is, n is nonintegral. This necessarily must be the case, since n is an integrator setting. There will always be an error in setting, and a corresponding error in the output.

It is obvious that the constant term, A_0, will be independent of frequency errors, in fact the accuracy of this term is limited only by tracking errors, which now are neglected. The other integrals, however, contain n, and if this is nonintegral, then there will be error. The error is the difference between the true value and the computed value. If δ represents the nonintegral part of n, this error can be written as

$$\mathcal{E}_{A_n}=\frac{1}{\pi}\int_0^{2\pi}F(\theta)\cos n\theta d\theta-\frac{1}{\pi}\int_0^{2\pi}F(\theta)\cos(n+\delta)\theta d\theta \qquad (34)$$

$$\mathcal{E}_{A_n}=\frac{1}{\pi}\left|\int_0^{2\pi}F(\theta)[\cos n\theta-\cos(n+\delta)\theta]d\theta\right| \qquad (35)$$

Expanding the quantity in the bracket there results

$$\cos n\theta-\cos(n+\delta)\theta=2\sin\left(n+\frac{\delta}{2}\right)\theta\times\sin\frac{\delta}{2}\theta \qquad (36)$$

and since δ is very small, not greater than 0.01, the last factor can be approximated by a maximum value $\delta/2\times 2\delta=\delta\pi$. Equation 35 then becomes

$$\mathcal{E}_{A_n}\approx\frac{1}{\pi}\times 2\pi\delta\int_0^{2\pi}F(\theta)\sin\left(n+\frac{\delta}{2}\right)\theta d\theta \qquad (37)$$

$$\mathcal{E}_{A_n}\approx 2\delta\int_0^{2\pi}F(\theta)\sin n\theta\cos\frac{\delta}{2}\theta d\theta+2\delta\int_0^{2\pi}F(\theta)\cos n\theta\sin\frac{\delta}{2}\theta d\theta \qquad (38)$$

Making the same approximation as before

$$\mathcal{E}_{A_n}\approx 2\delta\pi B_n+2\pi\delta^2A_n\approx 2\pi\delta B_n \qquad (39)$$

The error in the B_n term can be written

$$\mathcal{E}_{B_n}=\frac{1}{\pi}\int_0^{2\pi}F(\theta)\sin n\theta d\theta-\frac{1}{\pi}\int_0^{2\pi}F(\theta)\sin(n+\delta)\theta d\theta \qquad (40)$$

$$\mathcal{E}_{B_n}=\frac{1}{\pi}\int_0^{2\pi}F(\theta)[\sin n\theta-\sin(n+\delta)\theta]d\theta \qquad (41)$$

Expanding the quantity in the bracket there results, for δ very small

$$\mathcal{E}_{B_n}\approx -2\delta\int_0^{2\pi}F(\theta)\cos\left(n+\frac{\delta}{2}\right)\theta d\theta \qquad (42)$$

$$\mathcal{E}_{B_n}\approx -2\delta\int_0^{2\pi}F(\theta)\cos n\theta\cos\frac{\delta}{2}\theta d\theta+2\delta\int_0^{2\pi}F(\theta)\sin n\theta\sin\frac{\delta}{2}\theta d\theta \qquad (43)$$

Again making the same approximations as previously

$$\mathcal{E}_{B_n}\approx -2\delta\pi A_n+2\pi\delta^2B_n\approx -2\pi\delta A_n \qquad (44)$$

Discussion

R. Berkowitz (Moore School of Electrical Engineering, University of Pennsylvania, Philadelphia, Pa.): Since the completion of Mr. Charp's paper, some additional test work has been done on the Fourier coefficient harmonic analyzer at the Moore School of Electrical Engineering. Fourier coefficients were obtained both by the machine and by numerical computations for several types of functions, including triangular wave, approximation to random noise data made up of straight line segments, and composite sinusoidal wave containing 20 harmonics. In the discussion to follow the equations of operation are stated in simplified form and some conclusions resulting from the above mentioned tests as to sources of error and accuracy are presented.

Simplified Equations of Counter Outputs

Let A_{0c}, A_{nc}, B_{nc} T_c be the changes during a run of the readings of the A_0, A_n, B_n and "time" counters, respectively, and let $f_c + 97{,}500$ be the reading of the frequency counter. The curve to be analyzed is a function $y(x)$ plotted versus x starting at $x = 0$ on a piece of paper no larger than 5 inches (ordinates) by 10 inches (abscissas). Let u_y and u_x be respectively the numbers of y-units and x-units plotted per inch and let y_0 be that value of the ordinate corresponding to the machine zero (that value of ordinate occurring at the midpoint of the 5-inch maximum range).

The equations of operation are:

For the time counter (independent variable)

$$x = u_x T_c/45 \quad \text{or} \quad T_c = 45\, x/u_x \tag{1}$$

Frequency setting—causes Scotch yoke to generate $\sin 2\pi fx$ and $\cos 2\pi fx$, where

$$f = f_c/(250\, u_x) \quad \text{or} \quad f_c = 250\, u_x f \tag{2}$$

For A_0 counter reading

$$A_{0c} = \frac{115.2}{u_y u_x} \int_0^x [y(x) - y_0] dx \tag{3}$$

For A_n counter reading

$$A_{nc} = \frac{115.2}{u_y u_x} \int_0^x [y(x) - y_0] \cos 2f\pi x\, dx \tag{4}$$

For B_n counter reading

$$B_{nc} = \frac{115.2}{u_y u_c} \int_0^x [y(x) - y_0] \sin 2\pi fx\, dx \tag{5}$$

For harmonic analysis only one reading is taken for each frequency setting, at $x = x_m$, the highest value of the abscissa. Thus:

The final time counter reading

$$T_c = 45 x_m/u_x \tag{6}$$

The frequency setting for nth harmonic

$$f = n/x_m; \quad \therefore f_c = 250n\, u_x/x_m \tag{7}$$

The A_0 counter reads

$$A_{0c} = \frac{57.6\, x_m}{u_y u_x} \cdot \frac{2}{x_m} \int_0^{x_m} [y(x) - y_0] dx \tag{8}$$

The A_n counter reads

$$A_{nc} = \frac{57.6 x_m}{u_y u_x} \cdot \frac{2}{x_m} \int_0^{x_m} y(x) \cos 2\pi n \frac{x}{x_m} dx \tag{9}$$

The B_n counter reads

$$B_{nc} = \frac{57.6\, x_m}{u_y u_x} \cdot \frac{2}{x_m} \int_0^{x_m} y(x) \sin 2\pi n \frac{x}{x_m}\, cx \tag{10}$$

Thus the Fourier coefficients A_n and B_n are given by

$$A_n = \frac{u_y u_x}{57.6 x_m} A_{nc} = \frac{u_y}{1.28 T_c} A_{nc} \tag{11}$$

$$B_n = \frac{u_y u_x}{57.6 x_m} B_{nc} = \frac{u_y}{1.28\, T_c} B_{nc} \tag{12}$$

$$A_0 - 2y_0 = \frac{u_y u_x}{57.6 x_m} A_{0c} = \frac{u_y}{1.28\, T_c} A_{0c} \tag{13}$$

When the full 10-inch abscissa scale is used, $x_m/u_x = 10$, and thus

$$f_c = 25n \text{ (or one micrometer revolution per harmonic)} \tag{14}$$

$$T_c = 450 \tag{15}$$

$$A_n = \frac{u_y}{576} A_{nc} \tag{16}$$

$$B_n = \frac{u_y}{576} B_{nc} \tag{17}$$

$$A_0 = \frac{u_y}{576} A_{0c} + 2y_0 \tag{18}$$

Errors of the Machine Methods of Reduction

In actual runs to determine Fourier coefficients the following inaccuracies are immediately evident: (1) time counter does not read computed value at the end of the run; (2) Scotch Yoke has not returned to zero at the end of the run.

These effects are due to unavoidable slippage of integrators and looseness of gears. In many applications these effects are unimportant. However, if maximum accuracy is desired, the following procedure can be applied. At the end of a run, two values of the time counter reading are recorded: T_{c1}, the reading at which x_m has come under hairline, and T_{c2}, the reading at which the Scotch yoke has returned to zero. Suppose that $T_{c2} = T_{c1} + \Delta$. If for example Δ is greater than zero the implication is that the Scotch Yoke was moving too slow. Thus the run should be repeated with a higher value of f_c. In general, if Δ is greater in magnitude than some preassigned value depending on the degree of accuracy desired, the run should be repeated after the frequency counter setting has been changed by an amount δ, given approximately by

$$\delta \cong -\frac{11{,}250n}{T_{c1}^2} \Delta \tag{19}$$

In the normal case where $T_c \cong 450$, there results

$$\delta \cong -\frac{5}{90} n\ \Delta \text{ frequency counter divisions}$$

$$\delta \cong -\frac{5}{9} n\ \Delta \text{ frequency micrometer divisions,}$$

$$\text{since 25 counter divisions} = 250 \text{ micrometer divisions} \tag{20}$$

Note that in equations 19 and 20, n is the order of the particular harmonic being considered.

Accuracy of Fourier Harmonic Analysis

As a result of the tests made on the machine it is safe to say that with reasonably accurate tracking, harmonics of orders up to and including the 25th can be obtained with an expected error of less than approximately 20 counter divisions. It can be shown that maximum possible counter readings for any harmonic is about 735. Thus the expected error is less than 3 per cent of this maximum. It should be remembered that the actual number of counter divisions for a given harmonic will generally be considerably less than 735. As a result, the expected per cent error of a given harmonic will be correspondingly larger than the 3 per cent mentioned before.

Walter C. Johnson (School of Engineering, Princeton University, Princeton, N. J.): The harmonic analyzer described by Mr. Charp is ingenious and apparently very effective. The accuracy is quite good and is especially impressive at the higher harmonics. This speaks well for both the design and the construction of the device.

Regarding the analysis given in Appendix I for the maximum error to be expected from a slight mis-setting of the harmonic order, I agree with the author's general conclusion but not with his method of arriving at it. In finding the zeroes of the function $\cos(n + \delta)\theta - \cos n\theta$, he states in effect that if $\cos A = \cos B$, then $A = B + 2k\pi$, where k is an integer. From this he concludes that the zeroes of the function lie outside the interval $0 < \theta < 2\pi$, and so is able to use the mean-value theorem (equation 36)* to find the upper limit of the error. But the equation $\cos A = \cos B$ is satisfied also by $A = -B + 2k\pi$. Therefore, the function has additional zeroes given by

$$(n+\delta)\theta = -n\theta + 2k\pi$$

from which

$$\theta = \frac{k\pi}{n + \delta/2}$$

Thus, in the interval $0 < \theta < 2\pi$, the function has either $2n$ or $2n-1$ zeros, depending on whether the small number δ is positive or negative. The presence of the zeroes in the range of integration invalidates the result given in equation 41.

However, a direct calculation for a square wave shows a maximum error which is only double the limit indicated by equation 42, and it can be seen in an intuitive way that, so long as $\delta \ll 1$, the error can not be very large. The square wave defined by $f(\theta) = 1$ for $-\pi/2 < \theta < \pi/2$, $f(\theta) = -1$ for $\pi/2 < \theta < 3\pi/2$, has the Fourier coefficients $A_0 = 0$, $B_n = 0$, and

$$A_n = \frac{4}{n\pi} \sin \frac{n\pi}{2}$$

If the order of the harmonic is mis-set to $n + \delta$ instead of n, where $\delta \ll 1$, the coefficients become approximately

$$A_n' = \frac{4}{(n+\delta)\pi} \left(\sin \frac{n\pi}{2} - \delta\pi \cos \frac{n\pi}{2} - \pi\delta \right)$$

Approximating $1/(n + \delta)$ by $1/n - \delta/n^2$, the error is

---

* Editor's Note. Professor Johnson is referring to equation 36 in the preprint of the author's paper. This equation has since been corrected, as can be noted in the author's closure.

$$\epsilon = A_n - A_n' = \frac{2\delta}{n}\left(1 + \cos\frac{n\pi}{2} + \frac{2}{\pi n}\sin\frac{n\pi}{2}\right)$$

The function in parentheses has a maximum value of two when n is a multiple of four, whereas the maximum value of the function $f(\theta)$ is unity. Thus, for this function, the greatest error is double the limit given in equation 42.

S. Charp: Many thanks to Professor Johnson and Mr. Berkowitz for their comments. Notation of the additional zeros for the function $[\cos(n+\delta)\theta - \cos n\theta]$ mentioned by Professor Johnson were unfortunately omitted from the preprint of this paper. The existence of the additional roots was known and corrected for immediately after the preprint was issued. A slightly different analysis for the error due to mis-setting the frequency dial appears in this printed copy.

The use of the set of equations which were proposed by Mr. Berkowitz is optional on the part of the user of the harmonic analyzer. Equations are given in the body of the paper for the use of various scale factors which are easily related to those given by Mr. Berkowitz. The two sources of error noted by him may be the result of recent mechanical changes made in the original analyzer. For example, the machine as first constructed was equipped with a presetting time counter which automatically stopped the analyzer at the end of the prescribed period of the independent variable. Hence, the time counter always read the proper value at the end of a run.

The accuracy of a Scotch-yoke is, of course, dependent upon the tolerances set on the machining of its parts and the care taken in keeping it in adjustment. The fact that in recent operation the fiducial marker on the Scotch-yoke was not randomly offset from its zero position at the end of a series of runs would indicate that this source of error is not due to integrator slippage but rather to faulty maintenance, calibration, and operation of the analyzer. Improvements in these factors should increase the accuracy figure given by this discusser as well as increase the harmonic range of the machine bringing it closer to the fully designed value.

Application of the California Institute of Technology Electric Analog Computer to Nonlinear Mechanics and Servomechanisms

Synopsis: This paper describes the non-linear elements and circuit techniques used with the California Institute of Technology electric analog computer. Their application to nonlinear mechanical vibratory systems and nonlinear servomotors is discussed in detail. These techniques have been found to be generally suitable for representing single valued nonlinear functions of a dependent variable. Nonlinear springs, spring loaded backlash, and nonlinear damping factors can be readily simulated as well as saturation effects and other single valued nonlinearities in servomotors. Methods of analysis are illustrated for several typical problems including a nonlinear rotating mechanical system and an autopilot employing a solenoid-operated rate and position limited hydraulic motor. Numerous servos of this type have now been studied and correlation of computer solutions with actual servo test data have shown in every case that the mathematical equations presented here accurately describe this type of motor.

THE California Institute of Technology electric analog computer has now been used for the solution and general analysis of a sufficient number of nonlinear servomechanisms and nonlinear mechanical vibratory systems to warrant a general discussion of the electrical techniques and analogies suitable for such problems. This paper deals particularly with its application to problems involving single valued nonlinear parameters that are a function of one dependent variable. The more common types of such nonlinearity in mechanical vibratory systems are nonlinear springs, backlash, and nonlinear damping such a coulomb friction. Many types of servomechanisms have nonlinearities of sufficient importance that their effects should be considered in analyzing system performance. Some of these nonlinearities are in the control system itself; others are in the system to be controlled. In position type controllers nonlinearities are commonly in the form of velocity or position saturation effects or limits, backlash, coulomb friction, or servos of the "on-off" type. Saturation effects such as occur in motors and generators of speed controllers and voltage regulators are sometimes important. The nonlinearities existing in the systems to be controlled may be of many types. In mechanical systems they may be in the form of nonlinear damping factors or spring constants, or they may be in the form of limits to certain motions being controlled. Certain thermal processes are inherently nonlinear. Some types of autopilot problems require consideration of the nonlinearities in the aerodynamic equations.

The California Technology electric analog computer has been described in detail in previous papers.[1-4] Suitable multipliers and nonlinear function devices now have been developed to enable its use for the rapid solution of a large number of problems of this type. These are described in detail in reference 4, and are only discussed briefly here with reference to their application to circuit analogies. The basic elements now being used in this computer are listed in Figure 1. The form of symbolization shown is that used in the California Technical Analysis Laboratory for preparing analogous circuits.

Description of Nonlinear Functions Devices

The devices for simulating nonlinear functions of a dependent variable are of two general types designated here as the "type I" and "type II" nonlinear functions devices. The first of these is essentially a nonlinear resistor in that it produces voltages that are arbitrary functions of currents or vice versa. The second type produces voltages that are arbitrary functions of another voltage.

TYPE I—NONLINEAR FUNCTIONS DEVICE

Diodes which conduct freely in only one direction can be used as the basic elements of a nonlinear device. In order to avoid power supply problems and to minimize the "forward resistance," crystal diodes have been used generally instead of vacuum diodes. The "back resistance" of the former elements is sufficiently high to meet most of the requirements in practical problems. Although these diodes can be associated with general impedance elements, this is usually undesirable because the forward and back impedances are resistive in nature and are most readily combined with other resistances. Nonlinear impedances can be achieved with diodes, however, through the use of amplifiers as will be described later.

The two basic elements of the diode nonlinear resistance are the voltage clipper and the current limiter shown in Figure 2. For the voltage limiter, batteries are connected with polarity opposing the normal direction of current flow, so that until the voltage exceeds the battery voltage, the effective resistance of the circuit is very high and is equal to one-half the back resistance of one diode. After the voltage exceeds this value, the

effective resistance is very low, the forward resistance of one diode plus that of the battery. For a typical *1N35* crystal, the ratio of the two slopes of the voltage-current characteristic is approximately 10,000. The current limiter utilizes two large resistors, R_1, to produce circulating currents in the two diode loops. Until the current inserted at the terminal equals this circulating current, the net resistance of the network is low and twice the forward resistance of one diode, while for larger currents it becomes large, essentially equal to the resistance R_1 in parallel with the back resistance of one diode. The ratio of the slopes of the resulting characteristic is not as great as that for the voltage limiter because of the addition of the resistor R_1. However, values of 200-to-1 for this ratio can be readily achieved.

In both limiters, the ratio of slopes can be reduced to any desired value by insertion of resistors in parallel and in series with the diode branches. Such a modification forms the basis of the general nonlinear device shown in Figure 3. The adjustable resistors are made relatively large compared to the forward impedance of the crystals so that the variations of the latter with current do not affect the overall impedance appreciably. If the switches are all thrown to the left in Figure 3, each parallel branch will not conduct current until the terminal voltage rises above the battery voltage of that branch. The resulting current voltage characteristic is composed of a series of straight lines, with the slope of successive segments decreasing as the voltage rises. Such a characteristic is shown in curve "A" of Figure 3.

If the switches are thrown to the right, a different characteristic results. Each branch produces a circulating current which passes through R_0. The battery voltage E_0 is provided to give zero terminal voltage when no external current enters the terminals. As voltage is applied, the current which flows is determined by the effective resistance of all branches in parallel. As soon as the terminal voltage rises above the lowest branch battery voltage, the current in that branch ceases to flow, and the effective impedance of the device is raised. As the voltage exceeds the highest battery voltage, the impedance becomes equal to R_0 alone, the maximum value. The resulting current-voltage characteristic is one of constantly increasing slope, as shown in curve "B". By combination of branches of each type, a characteristic may be achieved whose slope is alternately increasing and decreasing, provided the slope always remains positive. Curve "C," Figure 3, is typical.

A nonlinear resistor with 22 parallel branches, 11 each for positive and negative voltages is shown in Figure 5. The simpler voltage and current limiter is shown in the same figure.

Type II—Nonlinear Functions Device

Although the first nonlinear device described is essentially a resistance element, another nonlinear device has been constructed which produces a voltage that is an arbitrary (though necessarily single valued) function of any voltage however derived. This generator is based upon a principle developed elsewhere.[6,7] It utilizes a cathode-ray tube and photo cell for viewing the cathode-ray tube screen. The quiescent position of the electron beam is set to one side of the tube and the photo cell output is amplified and applied to the plates with a polarity which will drive the beam to the other side. If an opaque template is placed on the surface of the tube, as shown in Figure 4, the beam spot will be driven below the edge of

the template until the light reaching the photo tube is just sufficient to produce a signal that will deflect the beam to the edge of the template. Since the beam will follow closely the template, and since the voltage required to deflect the beam is a linear function of the deflection, the output voltage of the device is proportional to the height of the template at the particular position of the beam. A generator of this type is shown in Figure 5. A typical characteristic is shown as viewed on an oscilloscope in Figure 4. A more detailed description of both of the nonlinear functions devices has been given elsewhere.[4]

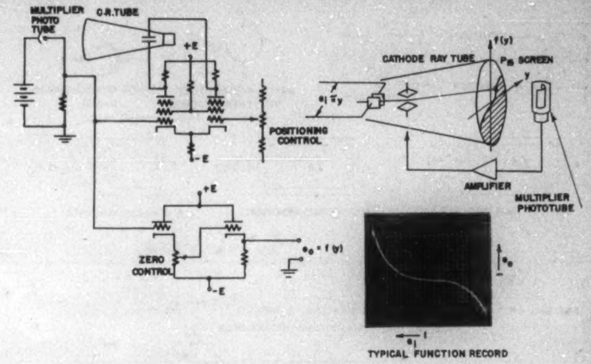

Figure 4. Schematic diagram of dependent variable device—type II

General Application of Nonlinear Devices

Voltage Clippers

In some physical systems a variable exhibits a linear characteristic until it reaches a limiting value which it cannot exceed. Such characteristics can be produced electrically with a voltage limiter if the voltage at some point in the electrical circuit can be made the analog of the variable in the physical system. The only important electrical requirement is that the voltage clipper be driven by a source with high impedance so that the forward resistance of the diode is very small compared with the source impedance. In typical cases the slope of the characteristic may be changed by a factor as large as 2,000.

As discussed later this principle can be used directly to simulate position and velocity stops in servomechanisms, coulomb friction, and backlash.

Current Limiters

A current limiter may be used in those cases where the current is analogous to a physical variable which is limited in its maximum value. Its application is discussed later with reference to rate limited hydraulic servos.

Nonlinear Gain Characteristics

The simulation of such nonlinear amplification characteristics as saturation effects in electronic amplifiers or rotating machines can be accomplished readily with either type of nonlinear functions device. The type II device need merely be inserted in cascade with linear amplifiers of the computer. The type I device also could be used in the same manner as illustrated later for simulating nonlinear springs.

However, it has usually been found more suitable to use it as a nonlinear feed-back resistor as shown in Figure 6. This type of circuit also is used where the resistance range provided by the type I device alone is too high.

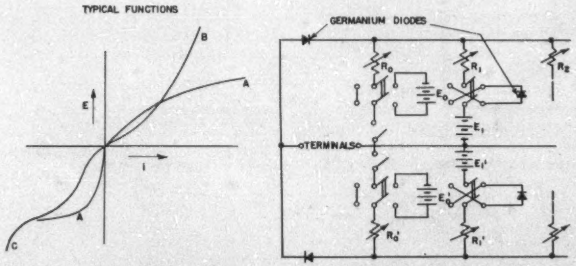

Figure 3. Schematic diagram of dependent variable device—type I

Nonlinear Impedances

The nonlinear terms arising in many physical or mathematical problems may be interpreted in the analog as nonlinear self or mutual impedances. It will be sufficient to describe methods of achieving nonlinear self impedances. The type I device must be used in conjunction with resistors to avoid unpredictable phase shift characteristics. In order to use this element, therefore, the voltage from a small impedance of the type specified must be applied to the nonlinear resistor by means of an amplifier, and the resulting nonlinear voltage reinserted in the circuit by means of another amplifier. Such a circuit and the resulting characteristic is shown in Figure 7. The use of the type II nonlinear device is shown in the same figure and requires no additional explanation.

As an example, suppose the charge flowing in a circuit is equal to a variable x, and a term $f(x)$ appears in the differential equation to be solved, then the impedance Z_0 would become a large capacitor and either nonlinear device would be adjusted to give an output voltage equal to $f(x)$. A correction would be applied if the voltage across the capacitor were appreciable in the circuit.

The accuracy obtained with the foregoing circuit techniques depends primarily upon how accurately it is attempted to simulate a given function. The type I device will simulate many functions with an error ranging from one to five per cent of the maximum value of the function. The type II device will simulate most functions to a somewhat greater accuracy, and is applicable to a wider variety of functions.

Nonlinearities in Mechanical Vibratory Systems

The preceding discussion makes it readily apparent that the nonlinear functions devices can be used to simulate most types of single valued nonlinearities occurring in mechanical systems. These are generally either nonlinear springs or damping factors. With the use of the force-voltage analogy, in which current is analogous to velocity and charge to position, it is evident that the nonlinear resistance devices can be used directly to simulate nonlinear mechanical damping. Their application to the analysis of problems involving coulomb friction has been discussed previously.[5]

NONLINEAR SPRINGS AND BACKLASH

The application of the nonlinear impedance circuits to mechanical systems with nonlinear springs and spring-loaded backlash is illustrated by the system of Figure 8. This is the rotating mechanical system of a radial aircraft engine that was studied quite extensively with the computer.

In this system all three shafts are geared and have appreciable spring-loaded backlash. In addition, shaft number 3 is nonlinear as is shown in Figure 9.

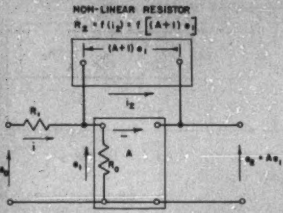

Figure 6. Circuit for nonlinear amplification factor or reduced impedance nonlinear resistor

e_0=input voltage from source of negligible impedance

$$e_1=\frac{R_2R_0e_0}{R_1R_2+R_2R_0+(A+1)R_1R_0}$$

if $R_1<<R_0$ and $A>>1$

$$e_1=\frac{R_2e_0}{R_2+(A+1)R_1}=\frac{e_0}{1+\frac{R_1}{R_2}(A+1)}$$

or if $\frac{R_1}{R_2}(A+1)>>1$

$$e_1=\frac{R_2e_0}{R_1(A+1)};\quad e_2=\frac{-AR_2e_0}{R_1(A+1)}$$

The following equations specify the system

$$\left.\begin{aligned}0&=Ip^2\theta_1+K_1(\theta_1-\theta_2)\\0&=I_2p^2\theta_2+K_1(\theta_2-\theta_1)+K_2(\theta_2-\theta_3)\\T&=I_3p^2\theta_3+K_2(\theta_3-\theta_2)+K_3(\theta_3-\theta_4)\\0&=I_4p^2\theta_4+K_3(\theta_4-\theta_3)\end{aligned}\right\}\quad(1)$$

where $p=\frac{d}{dt}$

If the spring characteristics were perfectly linear the analogous electric circuit would be that given in Figure 8(B) with simple capacitors representing the spring constants. The electric circuit equations would be the following

$$\left.\begin{aligned}0&=L_1p'^2q_1+\frac{1}{C_1}(q_1-q_2)\\0&=L_2p'^2q_2+\frac{1}{C_1}(q_2-q_1)+\frac{1}{C_2}(q_2-q_3)\\E_0&=L_3p'^2q_3+\frac{1}{C_2}(q_3-q_2)+\frac{1}{C_3}(q_3-q_4)\\0&=L_4p'^2q_4+\frac{1}{C_3}(q_4-q_3)\\p'&=\frac{d}{dt'}\end{aligned}\right\}\quad(2)$$

By establishing values for an impedance base factor (a) a time base change factor $\left(n=\frac{t}{t'}\text{ or }\frac{d}{dt'}=n\frac{d}{dt}\right)$ and a forcing functions ratio $r=\frac{T_0}{E_0}$ the following electrical parameters can be determined

$$L_1\ldots\ldots=I_1\frac{a}{n^2};\ \frac{1}{C_1}\ldots\ldots=aK_1;$$

$$\theta=arq;\ T=\frac{E}{r}\ \ldots\ldots\quad(3)$$

In the analysis of nonlinear problems of this sort, the proper representation of initial conditions is more difficult than for linear systems. This can be best illustrated by considering a specific type of disturbance, namely the torques produced by a cylinder misfire under a given load condition.

To simplify the initial conditions and the representation of the nonlinear springs for such a case a change can be made in the co-ordinate specifying the system such that the steady-state values of all functions are eliminated. Thus

$$T_0'=T_0-T_{0_{ss}};\ T_1'=T_1-T_{1_{ss}};$$
$$\theta_1'=\theta_1-\theta_{1_{ss}};\ \ldots\ldots\quad(4)$$

This changes the stress-strain curves representing the nonlinear springs in the manner illustrated by Figure 9(B). As shown in Figure 8(B) voltage clippers were used in the circuits of K_1 and K_2 to simulate the backlash. For shaft number 3 both the backlash and change of spring constant were simulated with the circuit of the type I functions device. However, in Figure 8(C) only those elements required are illustrated to clarify a detailed description of the analogy.

Referring to Figure 9(C) the charge flowing through the spring analogy circuit represents the strain and the voltage across it represents the stress. The analogous circuits of Figure 8 are actually positive self-impedance circuits that alter the effective capacities of the condensers C_1 and so forth, by a variable gain which is a function of (q_3-q_4) and is adjusted to properly fit the desired stress-strain curve. When the voltage E_1 exceeds the clipper voltage E_{c1} and the voltage E_2 is less than clipper voltage E_{c2}, Figure 8(C), the amplifier circuit has its maximum gain and the analogous spring factor for K_3 is a maximum given by the equation

$$aK_{3\max}=\frac{1}{C_{\min}}=\frac{1+kA_1A_2}{C_3}\quad(5)$$

where

$$k=\frac{R_1}{R_0+R_1}$$

Referring again to Figure 8(C), the backlash characteristic is simulated with the diode voltage clipper (E_{c1}). Whenever the voltage A_1E_0 plus E_1 is less than E_{c1} the clipper acts like an open circuit and amplifier A_2 puts out no voltage. Under these conditions the spring constant is

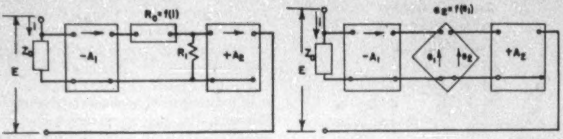

Figure 7. Circuits for obtaining nonlinear impedances with arbitrary functions devices

$$E=Z(i)i$$

$$Z(i)=\left(1+\frac{A_2f(A_1Z_0i)}{i}\right)$$

---

very low and equal to the following

$$aK_{3\min}=\frac{1}{C_3} \tag{6}$$

It will have this characteristic over a range of q_0 given by the following equation

$$\frac{q_0}{C_3}A_1=2E_{c1};\ \Delta E=\frac{2E_{c1}}{A_1} \tag{7}$$

This slope can be made negligible by using a large value for A_1A_2 and C_3.

The stress-strain curve is shifted to the proper zero position by adjusting E_1 to satisfy the relation

$$A_2(E_1-E_{c1})=\frac{T_a}{r} \tag{8}$$

and then the actual circuit voltage is set to zero by adjusting E_3 until

$$E_3=-A_2(E_1-E_{c1}) \tag{9}$$

Additional changes in the spring constants are accomplished by additional voltage clippers such as E_{c2}. The spring constant above this level is given by the equation

$$aK=\frac{1+\frac{R_a}{k}A_1A_2}{C_3} \tag{10}$$

where

$$R_a=\frac{R_1R_2}{R_1+R_2}$$

Smooth variations in the spring factor can be accomplished by replacing the second voltage clipper with the arbitrary functions device type II.

The resistance R_n could be inserted to add enough negative resistance to the circuit to cancel the effect of the resistance at the output terminals of amplifier A_2 should it be appreciable. However, the positive gain amplifiers used in the computer have an impedance of only one ohm so that such compensation is rarely necessary. The voltages E_1 and E_2 are obtained by adjustment of the d-c amplifier zero-control. Figure 10 presents typical solutions for the transient torque pulse resulting from a single cylinder misfiring. As mentioned before, this was simulated as an applied voltage pulse having no steady-state value.

Another nonlinear spring problem studied with the computer is illustrated in Figure 11. This represents a one degree of freedom mechanical system (having a nonlinear spring) that is controlled with a servo using rate and position feedback. Figure 11 shows typical solutions for both the controlled and uncontrolled system under the influence of a suddenly applied constant disturbance torque. Linear feedback only is shown. However, this system was studied with nonlinear position feedback. It is readily apparent that if the servo time delays are not too great, the system can be linearized by the use of a nonlinear position feed-back characteristic that just counteracts the nonlinearity of the spring.

Nonlinear Servomotors

During the past year and a half the California Technology computer has been used extensively for the design analysis of guided missile control systems. This work has all been of a restricted nature and the studies cannot be described in detail. However, the analog techniques themselves are of sufficient interest to merit discussion. In most of these studies the aerodynamical equations have been linearized but some have included the effects of angle of attack and interaction between the three degrees of freedom of the missile. The latter type have included studies of "stabilized" platforms.

RATE AND POSITION LIMITED HYDRAULIC SERVO SYSTEMS

Several types of servomotors have been analyzed. One of the most important of the nonlinear motors studied extensively is the "rate limited" hydraulic motor. In

Figure 13. Electrical analog for rate and position limited hydraulic servomotors

the valve. Such a motor can generally be quite accurately specified by the mathematical equations of Figure 13. These equations are derived in the Appendix together with the electrical analogy. There both the electrical and mechanical elements of the solenoid are represented by one lumped transfer function. This usually provides a sufficiently accurate analogy. However, if desired the complete analogy for both the electrical and mechanical elements of the solenoid can be used. The nonlinearities in motors of this type can usually be accurately specified by assigning a definite maximum value to the rudder velocity and assuming the system to be linear below these limits. Rudder position stops can be treated in the same way.

Referring to the Appendix and Figure 13, these limits are accomplished with voltage and current limiters. It was found that the velocity limitations for some motors (although sharply defined) had a saturation characteristic which was not perfectly flat. This type of characteristic was studied by using an arbitrary functions device instead of the simple voltage clipper. The results of the study showed that sufficiently accurate results could always be obtained with the simple voltage clipper.

Typical impulse and steady-state sinusoidal response characteristics of a servomotor are shown in the computer solutions of Figure 12. Analog computer analyses have been made for systems using this type of motor in which the numerical parameters were obtained in several ways. In some cases the servo

Figure 16. Electrical analog—rate and position limited hydraulic autopilot

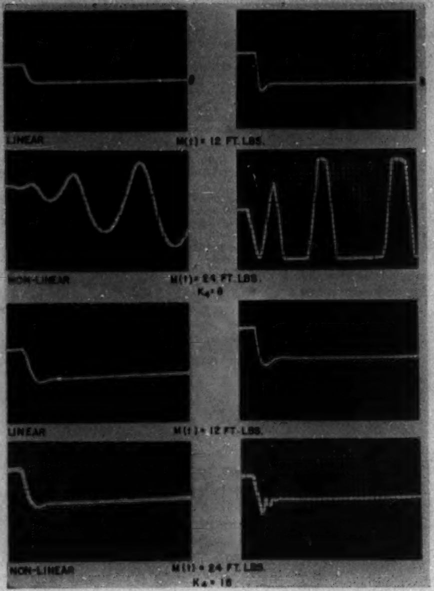

Figure 17. Response characteristics of autopilot system of Figure 15 instability induced by an applied torque exceeding the linear range of the control system, and corrected by an increase in K_4

$T_a = 0.06$ second; $T_\delta = 0$; $K_3 = 50$

parameters given in Figure 12 were obtained directly by test and used directly for specifying the proper analog parameters.

In other cases it was required to determine certain of the parameters by fitting frequency response curves as shown in Figure 14. Such curves can be run off very rapidly with a computer of this type so that it only requires a few hours to determine by trial and error the parameters that best simulate test data.

Figures 15 and 16 are typical examples of an autopilot employing a rate and position limited servomotor. This system was used for roll stabilization and the simplified form for the aerodynamic equations is shown. In the analogy, Figure 16, is shown a modified version of the motor analogy which can be used if the motor transfer function, Figure 13, can be expressed as a quadratic instead of a cubic equation. This analogy can be derived readily. In it the current i_1, Figure 16 is analogous to rudder velocity so that a current limiter is used for velocity limitation.

Computer solutions for the transient response characteristic of this type of servo system are given in Figure 17. These illustrate a condition found in several cases with the parameters of an actual proposed missile at certain points in its flight program. If optimum servo parameters were chosen from a perfectly linear analysis, well damped solutions such as given at the top of the figure result.

These solutions would correspond to those resulting from small disturbance torques in the actual systems. However, if the disturbance torque is sufficiently large the two nonlinearities can produce complete instability as illustrated by the second set of solutions. For this particular type of system the instability can be eliminated by increasing the rudder feed-back parameter K_4 as shown in the two bottom pairs of computer solutions, Figure 17.

With a computer of the type described here solutions can be obtained so rapidly that it is a relatively quick and simple matter to study the performance of a guided missile or autopilot over its complete range of flight conditions. Optimum servo parameters can thus be quickly determined.

In some cases a single set of servo parameters may be suitable. In others a schedule for varying the parameters may be desirable.

Appendix I. Derivation of the Equations and Analogy for Rate and Position Limited Hydraulic Servomotors

Let

V_s = control signal voltage
δ = rudder position angle
K_δ = feed-back constant from rudder position
e_0 = voltage applied to motor solenoid
$e_0 = V_s - K_\delta\delta$
M = mass of solenoid valve system
K = its spring constant
G = its damping factor
m = constant relating solenoid force to applied voltage e_c
k = constant relating rudder velocity to valve opening

$$\frac{d\delta}{dt} = p\delta = \frac{mk}{K}\cdot\frac{(V_s - K_\delta\delta)}{\frac{M}{K}p^2 + \frac{G}{K}p + 1} \tag{11}$$

δ and $p\delta$ are limited to either a specified maximum value or to a sharply defined saturation characteristic. Equation 11 can be rewritten as follows

$$p\delta = \frac{g(V_s - K\,\delta)}{\frac{p^2}{\omega^2} + \frac{2\tau}{\omega}p + 1} \tag{12}$$

where

$$g = \frac{mk}{K};\ \omega = \sqrt{\frac{K}{M}};\ = \frac{G}{2\sqrt{KM}}$$

Solving for δ gives the following equation

$$\delta = \frac{V_s}{K\left(\frac{1}{gK_\delta\omega^2}p^3 + \frac{2\tau}{gK\delta\omega}p^2 + \frac{1}{gK\delta}p + 1\right)} \tag{13}$$

Electrical Analogy. Referring to Figure 12, it can be seen that if V_s' is the analogous control signal voltage the input voltage e_0 is:

$$e_0 = V_s' - A_3e_2 \tag{14}$$

where e_2 is analogous to δ. The voltage e_1 is analogous to $p\delta$ and given by the equation

$$e_1 = \frac{-A_1RC(V_s' - A_3e_2)}{T_1(LCp^2 + RCp + 1)} \tag{15}$$

where T_0 is time constant of first integrating circuit.
As the relation between e_1 and e_2 we have the equation

$$e_2 = \frac{-A_2e_1}{T_0p} \tag{16}$$

where T_0 is the RC time constant of the second integrating circuit. Combining equations 14, 15, and 16

$$pe_2 = \frac{A_1A_2RC(V_s' - A_3e_2)}{T_1T_0(LCp^2 + RCp + 1)} \tag{17}$$

and solving for e_2

$$e_2 = \frac{V_s'}{A_3\left(\frac{T_1T_0L}{A_{123}R}p^3 + \frac{T_1T_0}{A_{123}}p^2 + \frac{T_1T_0}{A_{123}RC}p + 1\right)} \tag{18}$$

giving the transfer function analogous to that for the actual servo, equation 13. In this analogy the current in the *RLC* circuit is truly analogous to the solenoid position x which is proportional to $(p\delta)$. Thus by limiting this current with a current limiter the proper nonlinear conditions are imposed.

If a time base $\left(n=\frac{t}{t'}\right)$ is used where t' is computer time base and t actual time base the following relationships must be satisfied by the analogy

$$\left.\begin{aligned} &A_2=K_\delta & &\frac{T_1T_0}{A_{12}}=\frac{2}{2g\omega} \\ &\frac{T_1T_0L}{A_{12}R}=\frac{1}{n^2g\omega^2} & &\frac{T_1T_0}{A_{12}RC}=\frac{1}{ng} \end{aligned}\right\} \tag{19}$$

The following relationships establish the clipping current and voltages necessary to simulate the maximum permissible values for rudder velocity and position.

$$\text{Let } e_2=r\delta \text{ then } e_{2\max}=r\delta_{\max} \tag{20}$$

when e_2 and δ are expressed in volts and radians respectively

$$pe_{2\max}=nrp\delta_{\max}$$

or from equation 6

$$e_{1\max}i_{\max}R=\frac{T_0nr}{A_2}\,p\delta_{\max} \tag{21}$$

It should be noted that the rudder position and velocity limitations can be made different for the two directions. Equations 20 and 21 can be combined to give the following required relation between the two clipping voltages

$$\frac{e_1}{e_2}=\frac{T_0n}{A_2}\,\frac{(p\delta_{\max})}{(\delta_{\max})} \tag{22}$$

Summary of Transformations Useful in Constructing Analogs of Linear Vibration Problems

JAMES P. CORBETT
NONMEMBER AIEE

THIS PAPER is concerned with the problem of representing linear vibrating systems in terms of electric circuits. The system under study is represented by a system of ordinary differential equations, linear, with constant coefficients. Such a system has an electric circuit representation if the vibrations are of stable type. However, the realization may require the use of ideal transformers and ideal unilateral impedances, and the number of such devices may be excessive. Again, the realization may require an excessive range of impedance values or may require linear behavior over too great a range of frequencies.

Difficulties arising from frequency requirements usually can be evaded by changes of time scale which compress the frequency range. Difficulties concerning the numerical ranges of impedance elements, capacitors for example, generally are eliminated by a combination of a change of time scale and a change of scale of current or charge.

In standard works it is shown that a system of linear differential equations with constant coefficients can be reduced to a triangular system by use of a system of multipliers with constant determinant. The use of a transformation of this type can result in considerable simplification. It is possible to alter the essential type of coupling appearing between loops of the circuits by this means. This transformation is particularly valuable, since it does not alter the dependent or independent variables and introduces only rational functions of the original parameters.

If the original system is expressed in terms of operators, it appears as an ordinary system of linear algebraic equations. In matrix form, this last transformation is simply a multiplication of this system on the left by a nonsingular matrix of constant determinant, that is, a set of row transformations of the original matrix. A corresponding column transformation of the system can be made—multiplication on the right by a nonsingular matrix of constant determinant. This transformation introduces new dependent variables, but there are cases in which this transformation can be kept sufficiently simple for practical use. By the use of the foregoing transformations, many systems which otherwise would be difficult or unwieldy are found to have simple passive representations.

A simple treatment of changes of independent variable for a general differential equation is given. Here the defining relationship among the derivatives may have simple discontinuities. The importance of this lies in emphasizing the way in which initial conditions are transformed. When the system to be analoged contains a nonlinear element or a simple discontinuity, the realization of initial or boundary conditions in the analog must be given careful attention. Even for linear systems, there is always the possibility of obtaining simplification in the analog through attention to the realization of a suitable set of initial conditions. In this last connection, the following important fact should be pointed out. In constructing an analog, it may be possible to avoid the necessity for exact simulation of an active element by proper attention to the initial conditions under which the analog is operated.

Change of Time Scale

It will suffice to illustrate this process for the equation

$$L\frac{d^2y}{dt^2}+R\frac{dy}{dt}+Ky=0 \qquad (1)$$

Let $y = f(t)$ be a solution of equation 1 and let $u = \eta t$ be the equation defining the change of time scale.

Then

$$y=\phi(u)=f(u/\eta) \qquad (2)$$

and differentiating this last equation with respect to t we obtain

$$\frac{dy}{dt}=\phi'(u)\frac{du}{dt}=\eta\phi'(u)$$

$$\frac{d^2y}{dt^2}=\eta^2\phi''(u) \qquad (3)$$

Substituting these values in equation 1

$$\eta^2L\phi''(u)+\eta R\phi'(u)+K\phi=0 \qquad (4)$$

Thus, $y = \phi(u)$ is a solution of the equation

$$\eta^2L\frac{d^2y}{du^2}+\eta R\frac{dy}{du}+Ky=0 \qquad (5)$$

Conditions under which this process is reversible are given in the Appendix. That is, given a solution $y = \phi(u)$ of a transformed differential equation, state conditions under which $y = f(t) = \phi[u(t)]$ is a solution of the original differential equation.

One use of this transformation is in obtaining a "dimensionless" form of a differential equation, as in the following example. Let the differential equation be

$$a_0y'''+a_1y''+a_2y'+a_3y=0 \qquad (6)$$

Set

$$a_3y=z$$

obtaining

Paper 49-166, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer General Meeting, Swampscott, Mass., June 20–24, 1949. Manuscript submitted November 26, 1948; made available for printing May 5, 1949.

James P. Corbett is with the Aerial Measurements Laboratory, Northwestern University, Evanston, Ill.

$$(a_0/a_3)z'''+(a_1/a_3)z''+(a_2/a_3)z'+z=0 \qquad (7)$$

Let

$$w(u)=z(\eta t)$$
$$\eta=(a_3/a_0)^{1/3}$$

then

$$w'''+(a_1/a_3)(a_3/a_0)^{2/3}w''+(a_2/a_3)(a_3/a_0)^{1/3}w'+w=0 \qquad (8)$$

which is a useful canonical form.[1]

Note that the initial conditions for operation of the analog are transformed according to equations 2 and 3.

Left Multiplication by a Nonsingular Matrix

In considering the system

$$U_i=\sum_{j=1}^{n}F_{ij}(D)y_j=0,\ (i=1,2,\ldots,n) \qquad (9)$$

a common procedure is to derive new equations by the operations of differentiation, multiplication by a constant, and addition or subtraction of the equations U_i. In other words the polynomials $F_{ij}(D)$ are considered as algebraic quantities, and the equations are manipulated according to the ordinary rules of algebra. If such operations are performed without restriction, extraneous solutions may be introduced, and the derived system will not form the basis for a usable analog. The foregoing process is equivalent to replacing the system of equation 9 by the system

$$V_k=\sum_{i=1}^{n}A_{ki}(D)U_i,\ (k=1,2,\ldots,n) \qquad (10)$$

where the elements, $A_{ki}(D)$, of the matrix are polynomials in D, and where the determinant of the matrix is not identically zero. The systems of equations 9 and 10 are equivalent if any solution of either is a solution of the other.

As an example, consider the system

$$U_1=(D+1)(D+2)y_1-(D+3)y_2=0$$
$$U_2=\qquad (D+2)y_1+\qquad y_2=0 \qquad (11)$$

Multiply the second equation of this system by $(D+1)$ and add to the first, obtaining

$$V_1=U_1+(D+1)U_2=-2y_2=0 \qquad (12)$$

and set

$$V_2=U_1=(D+1)(D+2)y_1-(D+3)y_2=0 \qquad (13)$$

The system consisting of the pair of equations 12 and 13 has among its solutions

$$y_2=0\quad y_1=e^{-t} \qquad (14)$$

which does not satisfy the original system. The solutions of the system of equation 11 are

$$y_2=0\quad y_1=ae^{-2t} \qquad (15)$$

This example shows the necessity for care in algebraic manipulation of a system of differential equations.

The systems of equations 9 and 10 are equivalent if, and only if, the determinant of the matrix $[A_{ki}(D)]$ is a constant (independent of D) different from zero. In the preceding example the value of this determinant is $-(D+1)$; hence equations 11 and equations 12 and 13 are not equivalent.

For our purpose, an important property of a transformation of the present type is that a system of differential equations of the form of equation 9 can be reduced to an equivalent triangular system

$$U_i=\sum_{j=1}^{n}F_{ij}(D)y_j=0 \qquad (16)$$

where $F_{ij}(D)=0$ if $i>j$, that is, in the matrix, all elements below the principal diagonal are zero. This reduction can be accomplished with any ordering of the variables, $y_1,\ldots.y_n$.[2]

It may be well to point out that solutions of the system of equations 9 by determinant theory will lead merely to the system

$$\Delta(D)y_i=0\ (i=1,2,\ldots n) \qquad (17)$$

where Δ (D) is the determinant of the system matrix, a result which may or may not be equivalent to the original system.

If the reduction to an equivalent triangular form is accomplished, the last equation of the system will be

$$F_{nn}(D)y_n=0 \qquad (18)$$

and hence the behavior of the element represented by y_n is described by the single differential equation given in equation 18.

A transformation of the foregoing type can be used to eliminate certain couplings from the system, as in the following example

$$U_1=(L_{11}D^2+R_{11}D)y_1-R_{12}Dy_2=0$$
$$U_2=\qquad -R_{21}D\ y_1+K_{22}\ y_2=0 \qquad (19)$$

If the voltage $R_{12}D\ y_2$ is to be supplied from the capacitor voltage $K_{22}\ y_2$, a differentiating amplifier would be required. This coupling can be eliminated in the following manner. Let the system of equations 19 be replaced by the system

$$V_1=aU_1+bDU_2=0$$

$$V_2=\qquad U_2=0 \qquad (20)$$

The equations making up the last system are

$$[(aL_{11}-bR_{21})D^2+aR_{11}D]y_1-(aR_{12}-bK_{22})Dy_2=0-R_{21}Dy_1+K_{22}y_2=0 \qquad (21)$$

Set

$$(aR_{12}-bK_{22})=0$$

then

$$a/b=K_{22}/R_{12}$$

If all the parameters of the system of equations 19 are positive, then a/b is positive.

The coefficient,

$$aL_{11}-bR_{21}$$

becomes

$$b(L_{11}K_{22}/R_{12}-R_{21})$$

If a and b are both positive, this last term will have the same sign as R_{11}, that is, a positive sign only if

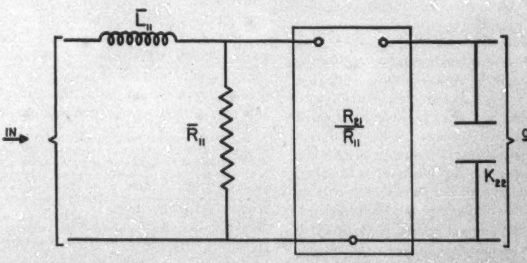
$$L_{11}K_{22}-R_{12}R_{21}=0$$

The characteristic determinant of the original system is

$$(L_{11}K_{22}-R_{12}R_{21})D^2+R_{11}K_{22}D \qquad (22)$$

Hence, if the system is stable, the first coefficient must be positive and the trans-

Figure 1. Circuit representation of equations 23



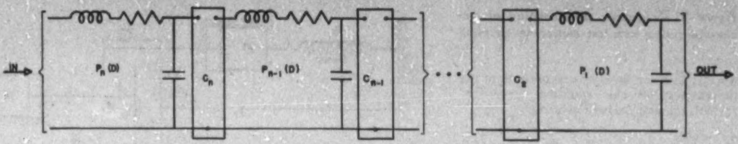


Figure 2. Circuit representation of differential equation, equations 24

formation can be made in the desired manner.

The new system, equation 20, therefore has the form

$$\begin{aligned}(\bar{L}_{11}D^2+\bar{R}_{11}D)y_1 \qquad &=0\\ -R_{21}D\ y_1+K_{22}y_2&=0 \qquad (23)\end{aligned}$$

where

$$\bar{L}_{11}=aL_{11}-bR_{21}>0$$
$$\bar{R}_{11}=aR_{11}$$

and is representable by the circuit shown in Figure 1.

A possible analog which will represent solutions of the differential equation

$$P_1(D)P_2(D)\dots P_n(D)y=1 \qquad (24)$$

will be shown to be the following system.

Let the system of equations be given

$$U_1=P_1(D)y_1-y_2=0$$
$$U_2=P_2(D)y_2-y_3=0$$
$$\cdot \quad \cdot \quad \cdot \quad \cdot$$
$$U_{n-1}=P_{n-1}(D)y_{n-1}-y_{n-1}=0$$
$$U_n=P_n(D)y_n=1 \qquad (25)$$

where

$$P_k(D)=a_kD^2+b_kD+c_k,\ (k=1,\ 2,\ \dots,\ n)$$

Replace this system by the equivalent system

$$V_1=U_1$$
$$V_2=P_2U_1+U_2$$
$$V_3=P_3P_2U_1+P_3U_2+U_3$$
$$\cdot \quad \cdot \quad \cdot \quad \cdot$$
$$V_k=P_kV_{k-1}+U_k \qquad (26)$$

and note that the determinant of this system is equal to one.

These equations when expanded in terms of the original system become

$$P_1(D)y_1-y_2=0$$
$$P_1(D)P_2(D)y_1-y_3=0$$
$$P_1(D)P_2(D)P_3(D)y_1-y_4=0$$
$$\cdot \quad \cdot \quad \cdot \quad \cdot$$
$$P_1(D)P_2(D)\dots P_n(D)y_1=1 \qquad (27)$$

The equivalent system, equations 25, then is an analog for the differential equation given in equations 24, as shown in Figure 2.

Transformation of Dependent Variables

We begin with the system

$$U_i=\sum_{j=1}^{n}F_{ij}(D)y_j=0,\ (i=1,\ 2,\ \dots,\ n) \qquad (28)$$

with the determinant of the matrix $(F_{ij}(D)) \neq 0$.

Let a transformation be defined by

$$y_j=\sum_{k=1}^{n}A_{jk}(D)z_k,\ (j=1,2,\dots,\ n) \qquad (29)$$

where the elements $A_{jk}(D)$ are polynomials in D.

The system of equations 28 then becomes

$$V_i=\sum_{j,k=1}^{n}F_{i}\ (D)A_{jk}(D)z_k=0,$$
$$(i=1,\ 2,\ \dots,\ n) \qquad (30)$$

If the determinant of the matrix $[A_{jk}(D)]$ is nonzero and independent of D, the variables z are uniquely expressible as

$$z_k=\sum_{j=1}^{n}B_{kj}(D)y_j,\ (k=1,\ 2,\ \dots,\ n) \qquad (31)$$

where $B_{kj}(D)$ are the elements of the matrix inverse to $[A_{ij}(D)]$ and, since the determinant of the latter matrix is constant, the elements $B_{kj}(D)$ are polynomials in D.

If z_k is a solution of equations 30, then the functions y_j defined by equation 29 are seen to be a solution of equations 28. If (y_j) are a solution of equations 28, then the functions (z_k) defined by equations 31, substituted into equations 30, yield

$$V_i=U_i=0$$

and hence these functions are solutions of equations 30.

This transformation may be exploited in a manner similar to that indicated in the example given under "Left Multiplication by a Nonsingular Matrix." This last example amounted to a row transformation of the matrix $[F_{ij}(D)]$. The present transformation represents a column transformation of this matrix.

The following example illustrates a transformation of this kind. We previously considered a system of equations

$$\begin{aligned}U_1&=(L_{11}D^2+R_{11}D)y_1-R_{12}Dy_2=0\\ U_2&=\qquad -R_{21}D\ y_1+K_{22}\ \ y_2=0 \qquad (32)\end{aligned}$$

Set

$$y_1=z_1$$
$$y_2=(R_{21}/K_{22})Dz_1+z_2 \qquad (33)$$

and the system of equations 32 becomes

$$\begin{aligned}V_1&=[(L_{11}-R_{12}R_{21}/K_{22})D^2+R_{11}D]z_1-\\ &\qquad R_{12}Dz_2=0\\ V_2&=\ \ K_{22}\ \ z_2=0 \qquad (34)\end{aligned}$$

and, as has been shown, if the original system was stable, the term $(L_{11}-R_{12}R_{21}/K_{22})$ is positive.

Let the system of equations 34 be replaced by

$$W_1=V_1+\frac{R_{12}}{K_{22}}DV_2=0$$
$$W_2=V_2 \qquad (35)$$

which, when expanded, becomes

$$W_1=\bar{L}D^2+\bar{R}Dz_1=0$$
$$W_2=K_{22}z_2=0 \qquad (36)$$

where

$$\bar{L}=(L_{11}-R_{12}R_{21}/K_{22})$$
$$\bar{R}=R_{11}$$

Appendix I. Change of Independent Variable in a System of Ordinary Differential Equations

Let a typical differential equation of the system have the form

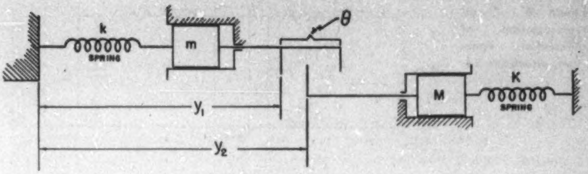
$$F(x,\ y,\ dy/dt,\ \dots\ d^ny/dt^n)=0 \qquad (37)$$

where the arguments y, $dy/dt, \dots,\ d^ny/dt^n$ may be regarded as symbols for the set of arguments $y=(y_i)$ together with the successive derivatives of the elements y_i.

Suppose that a solution of equations 37, $y=f(x)$, is known. Let $x=x(u)$ be a transformation from the variable u to the variable x. In the range of definition of $x(u)$, it will be supposed that the first n derivatives of $x(u)$ exist, and that $dx/du \neq 0$ throughout the range.

Under these circumstances the inverse transformation $u=u(x)$ exists and has the same differentiability properties as $x(u)$. The successive derivatives of the function

Figure 3. Schematic representation of mechanical system with lost motion in coupling



$y=f(x)$ then can be expressed in terms of the derivatives of the equation $y=\phi(u)=f[x(u)]$, the first derivative being

$$\frac{dy}{dx}=\frac{du}{dx}\frac{dy}{du} \tag{38}$$

By an induction it can be shown that

$$\frac{d^py}{dx^p}=A_{1p}\frac{dy}{du}+A_{2p}\frac{d^2y}{du^2}+\ldots+A_{pp}\frac{d^py}{du^p} \tag{39}$$

where the quantities A_{kp} are integral functions of the derivatives of $u(x)$ and where in particular $A_{pp}=du/dx$.

Equations 37 are thus to be transformed by replacing the derivatives d^py/dx^p by the linear expressions given by equations 39. Equations 37 then have the form

$$G\left(u, \frac{dy}{du}, \frac{d^2y}{du^2}, \cdots \frac{d^ny}{du^n}\right)=0 \tag{40}$$

In order to see that a solution of equations 37 can be recovered from a solution $y=\phi(u)$ of equations 40, we note that the system of linear equations, equations 39, has a unique inverse, since the determinant of the system is

$$\left[\frac{du}{dx}\right]^p \neq 0$$

Since the inverse is known to be unique, it is unnecessary to solve for the quantities d^py/du^p from equations 39. Instead, the chain rule for differentiation yields directly

$$\frac{d^py}{du^p}=B_{1p}\frac{dy}{dx}+B_{2p}\frac{d^2y}{dx^2}+\ldots B_{pp}\frac{d^py}{dx^p} \tag{41}$$

Substitution of these expressions into equations 40 must reduce it to the original differential equation, equations 37.

These considerations show that if $y=f(x)$ is any solution of the system of equations 37, then $y=\phi(u)=f[x(u)]$ is a solution of the transformed system of equations 40, and conversely, if $y=\phi(u)$ is any solution of the system of equations 37, then $y=f(x)$, $f(x)=\phi[x(u)]$ is a solution of the original system.

An application of this result is to the equations representing a simple mechanical system in which there is coulomb friction. The functional relationship, equation 37, in this case will be represented by

$$my''+ky+\epsilon f=0 \tag{42}$$

m, k, f, are fixed real constants

where

$\epsilon=1$ if $y'>0$
$\epsilon=-1$ if $y'<0$
$y'=0$ and $y\geq f/k$, then $\epsilon=-1$
$y'=0$ and $y\leq -f/k$, then $\epsilon=+1$

$y'=0$ and $|y|<f/k$, then $\epsilon=-\frac{k}{f}y$

To change time scales, it is only necessary to know that a solution exists. If $u=\eta t$, we obtain,

$$m\eta^2z''+\eta kz'+\epsilon f=0 \tag{43}$$

with the same conditions as above on ϵ relative to the functions, $z(u)$ and $z'(u)$.

Another example is for a system in which "backlash" or "lost motion" is present. See Figure 3. In a simple case the system is represented by the equations

$$my_1''+ry_1'+ky_1=0$$

$$My_2''+Ry_2'+Ky_2=0 \tag{44}$$

for

$y_1<y_2<y_1+\theta$

For the conditions, $y_1=y_2$, or $y_2=y_1+\theta$ it will be assumed that new boundary conditions may be computed according to the laws of conservation of momenta and energy.

Let $y_2(t_0)-y_1(t_0)=\theta$. The boundary conditions then may be expressed as

$$M[y_2'(t_0-0)]^2+m[y_1'(t_0-0)]^2$$
$$=M[y_2'(t_0)]^2+m[y_1'(t_0)]^2$$

$$My_2'(t_0-0)+my_1'(t_0-0)$$
$$=My_2'(t_0)+my_1'(t_0) \tag{45}$$

Setting $u=\eta t$, $z_1(u)=y_1(u/\eta)$, $z_2(u)=y_2(u/\eta)$, we obtain

$$\eta^2mz_1''+\eta=z_1'+kz_1=0$$

$$\eta^2Mz_2''+\eta Rz_2'+Kz_2=0 \tag{46}$$

and the boundary conditions become

$$M\eta^2[z_2'(u_0-0)]^2+m\eta^2[z_1'(u_0-0)]^2$$
$$=M\eta^2[z_2'(u_0)]^2+m\eta^2[z_1'(u_0)]^2$$

$$M\eta z_2'(u_0-0)+m\eta z_1'(u_0-0)$$
$$=M\eta z_2'(u_0)+m\eta z_1(u_0) \tag{47}$$

and the above equations are seen to be independent of the constant η.

Formulas and Tables for the Calculation of the Magnetic Field Components of Circular Filaments and Solenoids

FREDERICK W. GROVER
MEMBER AIEE

THE calculation of the magnetic field strength at any point, due to a current in a circular filament or in a solenoid, is a problem having not only a theoretical interest but a practical importance in the shielding of apparatus and in the design of instruments for the control of electron flow.

Series formulas, both for circular filaments and for solenoids, involving zonal harmonics, were derived by Gray,[1] and extended by Dwight[2] to cover all possible cases. Dwight also has derived[3] formulas in hypergeometrical series which apply to short solenoids, and has shown how to take into account the correction due to the actual distribution of the current in a rectangular section.

Russell[4,5] expressed the magnetic field components of a circular filament in terms of elliptic integrals. A very full account of existing formulas and the cases to which they apply is given in chapter 32 of Dwight's book Electrical Coils and Conductors.[6]

The present paper has for its purpose the derivation of further formulas, both for circular filaments and solenoids. Particular attention is paid to the problem of routine calculations of magnetic field strength. Tables are provided for facilitating the computations.

Methods of Deriving Formulas for Field of a Circular Filament

If an expression for the magnetic potential ω is available, then the axial component H_z and the radial component H_r of the magnetic field strength are found by $H_z=-\partial\omega/\partial x$ and $H_r=-\partial\omega/\partial y$.

This is the method by which were obtained existing formulas[1,2] in zonal harmonics. Unfortunately, these expressions are not very rapidly convergent in certain cases.

The Biot-Savart formula for the magnetic field intensity due to an element of current, may be integrated around the circuit. The usefulness of this as a general method of attack is limited by the difficulty of performing the integration. This method was used by Russell[4,5] in deriving his elliptical integral expressions for the magnetic field components of a circular filament.

Dwight[3,6] has shown that the field components of a circular filament may be obtained by differentiation of any formula for the mutual inductance of two coaxial circles. If M_0 is the mutual inductance of two coaxial circles, one of which is the given filament and the other of radius y is passed through the point P (x,y), then

$$H_z=\frac{NI}{10}\frac{1}{2\pi y}\frac{\partial M_0}{\partial y} \tag{1}$$

$$H_r=-\frac{NI}{10}\frac{1}{2\pi y}\frac{\partial M_0}{\partial x} \tag{2}$$

The dimensions are in centimeters, the current in amperes, M_0 in abhenrys, and H_z and H_r are in gausses. The factor N is introduced to cover the case of a circular coil of N turns and negligible cross section, whose mean radius is a.

This is a very useful method, in that the differentiations always will be possible. Dwight's formulas 2 and 8, pages 274 and 278 of reference 6, for H_z and H_r were derived by differentiating a series expression for M_0 due to Havelock,[7] which is especially suitable for the purpose, since the dimensions of the problem appear in simple form in the general term of the series. However, many other formulas for M_0 are known[8,9] from which also formulas for the magnetic field components of a circular filament may be derived.

It is interesting to note, in passing, the relations between formulas 1 and 2 and the well-known formulas for the mechanical force exerted between the two coaxial filaments. The mechanical force, exerted in the axial direction, on each element ds of the circular filament of radius y through point P carrying a current of $i/10$ amperes, is $(iH_r/10).ds$. Substituting for H_r from formula 2, this is

$$-\frac{iI}{100}\frac{1}{2\pi y}\frac{\partial M_0}{\partial x}.ds$$

and integrating around the filament, the total axial force is

$$-\frac{iI}{100}\frac{\partial M_0}{\partial x}$$

the familiar formula.

Similar reasoning, using formula 1 for H_z, leads to the known expression for the mechanical force tending to increase the radial dimension of the circular filament.

Formulas 1 and 2 applied to the Maxwell elliptic integral formula[11] for the mutual inductance of coaxial circular filaments, leads to the Russell formulas[4,5] for the magnetic field components of a circular filament. Since these also are expressed in elliptic integrals, they are especially useful as a starting point for obtaining other formulas, since the elliptic integrals may be expanded in such various ways as in hypergeometric series, in q series, and in arithmetico-geometrical-mean expressions. Of these possible

---

Paper 49-167, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer General Meeting, Swampscott, Mass., June 20–24, 1949. Manuscript submitted February 25, 1949; made available for printing May 5, 1949.

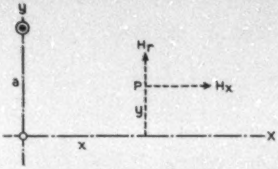

Figure 1. Field of circular filament, nomenclature

series only those in hypergeometric series will be considered here. The formulas obtained also may be derived by the use of formulas 1 and 2, but it is simpler to work from the Russell formulas.

Series Expansions for Circular Filaments

The Russell formulas are

$$H_x=\frac{2NI}{10r_1}\left[\frac{2a(a-y)}{r_2^2}\ E+(K-E)\right] \tag{3}$$

$$H_r=\frac{2NI}{10r_1}\left[\frac{2ax}{r_2^2}\ E-\frac{x}{y}(K-E)\right] \tag{4}$$

or, expressed in terms of space ratios

$$H_x=\frac{A}{\rho_1}\left[\frac{2(1-y/a)}{\rho_2^2}\ E+(K-E)\right] \tag{3a}$$

$$H_r=\frac{A}{\rho_1}\left[\frac{2x/a}{\rho_2^2}\ E-\frac{x}{y}\,(K-E)\right] \tag{4a}$$

where, as shown in Figure 1

a = radius of the filament
x, y = co-ordinates of the point P, referred to an origin at the center of the filament

$$r_1^2=(a+y)^2+x^2 \qquad \rho_1^2=(1+y/a)^2+\frac{x^2}{a^2}$$

$$r_2^2=(a-y)^2+x^2 \qquad \rho_2^2=(1-y/a)^2+\frac{x^2}{a^2}$$

$$A=2NI/10a$$

K and E are complete elliptic integrals with modulus given by $k^2=4ay/r_1^2$ and complementary modulus by $k'^2=r_2^2/r_1^2$. In Figure 1, the positive directions of H_x and H_r are as shown for the indicated direction of the current in the filament. From equations 3 and 4 it is evident that H_x reverses in direction for large values of y. H_r for a given value of y, changes sign in passing through the plane of the coil. These facts are in agreement with the familiar lines-of-force diagram of the filament.

Making use in equations 3(a) and 4(a) of the known expansions[12] of the elliptic integrals in powers, respectively, of k^2, k'^2, $\mu^2=k'^2/k^2=r_2^2/4ay$, and $\nu^2=k^2/k'^2=4ay/r_2^2$, and with the abbreviations $\lambda=\log_e 4/k'$ and $\lambda'=\log_e 4/\mu$, there result the following series expansions

$$H_x=\frac{\pi A}{\rho_1^3k'^2}\left[\left(1-\frac{k^2}{4}-\frac{3}{64}\,k^4-\frac{5}{256}\,k^6-\frac{175}{16{,}384}\,k^8-\frac{441}{65{,}536}k^{10}-\ldots\right)-\frac{3}{8}\,k^2\frac{y}{a}\left(1+\frac{k^2}{4}+\frac{15}{128}\,k^4+\frac{35}{512}k^6+\frac{735}{16{,}384}\,k^8+\ldots\right)\right] \tag{5}$$

$$H_r=\frac{3}{8}\ \frac{\pi A\dfrac{x}{a}\,\nu^2}{\rho_1^3}\left[1+\frac{k^2}{4}+\frac{15}{128}\,k^4+\frac{35}{512}\,k^6+\frac{735}{16{,}384}\,k^8+\ldots\right] \tag{6}$$

in powers of k^2, and

$$H_x=\frac{\pi A}{\rho_1^3k'}\left[\left(1+\frac{\nu^2}{4}-\frac{3}{64}\,\nu^4+\frac{5}{256}\,\nu^6-\frac{175}{16{,}384}\,\nu^8+\frac{441}{65{,}536}\,\nu^{10}-\ldots\right)-\frac{3}{8}\,\nu^2\frac{y}{a}\left(1-\frac{\nu^2}{4}+\frac{15}{128}\,\nu^4-\frac{35}{512}\nu^6+\frac{735}{16{,}384}\,\nu^8-\ldots\right)\right] \tag{7}$$

$$H_r=\frac{3}{8}\ \frac{\pi A\dfrac{x}{a}\,\nu^2}{\rho_1^3k'}\left[1-\frac{\nu^2}{4}+\frac{15}{128}\,\nu^4-\frac{35}{512}\,\nu^6+\frac{735}{16{,}384}\nu^8-\ldots\right] \tag{8}$$

in powers of ν^2. Also in terms of the complimentary modulus k'.

$$H_x=\frac{2A}{\rho_1^3k^2k'^2}\left[\left\{1+\frac{k'^2}{2}\left(\lambda-\frac{5}{2}\right)-\frac{5}{16}\,k'^4\times\left(\lambda-\frac{3}{20}\right)-\frac{9}{128}\,k'^6\left(\lambda-\frac{8}{9}\right)-\frac{65}{2{,}048}\,k'^8\left(\lambda-\frac{1{,}657}{1{,}560}\right)-\ldots\right\}-\frac{y}{a}\left\{1-\frac{3}{2}\,k'^2\left(\lambda-\frac{1}{2}\right)+\frac{3}{16}\,k'^4\times\left(\lambda+\frac{1}{4}\right)+\frac{3}{128}\,k'^6\left(\lambda-\frac{2}{3}\right)+\frac{15}{2{,}048}\,k'^8\left(\lambda-\frac{109}{120}\right)+\ldots\right\}\right] \tag{9}$$

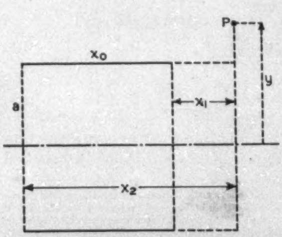

Figure 2. Field of thin solenoid or current sheet. Field at point P is difference of field due to two solenoids with point in end plane of each

$$H_r=\frac{2A\dfrac{x}{a}}{\rho_1^3k^2k'^2}\left[1-\frac{3}{2}\,k'^2\left(\lambda-\frac{1}{2}\right)+\frac{3}{16}\,k'^4\left(\lambda+\frac{1}{4}\right)+\frac{3}{128}\,k'^6\left(\lambda-\frac{2}{3}\right)+\frac{15}{2{,}048}\,k'^8\left(\lambda-\frac{109}{120}\right)+\ldots\right] \tag{10}$$

and in powers of μ^2

$$H_x=\frac{2A}{\rho_1^3\mu^2k}\left[\left\{1+\frac{1}{2}\,\mu^2\left(\lambda'+\frac{1}{2}\right)-\frac{1}{16}\,\mu^4\left(\lambda'-\frac{3}{4}\right)+\frac{3}{128}\,\mu^6\left(\lambda'-1\right)-\frac{25}{2{,}048}\,\mu^8\left(\lambda'-\frac{133}{120}\right)+\ldots\right\}-\frac{y}{a}\left\{1-\frac{3}{2}\,\mu^2\left(\lambda'-\frac{3}{2}\right)-\frac{9}{16}\,\mu^4\left(\lambda'-\frac{1}{12}\right)+\frac{15}{128}\,\mu^6\left(\lambda'-\frac{13}{15}\right)-\frac{105}{2{,}048}\,\mu^8\times\left(\lambda'-\frac{883}{840}\right)+\ldots\right\}\right] \tag{11}$$

$$H_r=\frac{2A\dfrac{x}{a}}{\rho_1^3\mu^2k}\left[1-\frac{3}{2}\,\mu^2\left(\lambda'-\frac{3}{2}\right)-\frac{9}{16}\,\mu^4\left(\lambda'-\frac{1}{12}\right)+\frac{15}{128}\,\mu^6\left(\lambda'-\frac{13}{15}\right)-\frac{105}{2{,}048}\,\mu^8\left(\lambda'-\frac{883}{840}\right)+\ldots\right] \tag{12}$$

These expressions have been checked by differentiation of the corresponding formulas[8,9,10] for M_0. In certain instances algebraic transformations have been applied to give more favorable numerical coefficients. In each case the factor A takes account of the current, number of turns, and the radius of the filament. The series involve space ratios only. Formulas 9 to 12 inclusive are useful for points near the filament and are very accurate for values of k'^2 and μ^2 less than about 0.2. Formulas 5 to 8, inclusive are very convergent for values of k^2 and ν^2 smaller than about 0.2 and find their usefulness for distant points. Formulas 11 and 12 are equivalent to Dwight's formulas 2 and 7, respectively, although expressed in more compact form. The other formulas are believed to be new.

In addition to the Russell formulas 3 and 4, other expressions in elliptic integrals may be derived by differentiation of other elliptic integral formulas[8,9,10] for M_0. Of these the most important is Maxwell's second formula.[11]

The resulting expressions are

$$H_x=\frac{A(\rho_1+\rho_2)}{\rho_1\rho_2k_1y/a}\left[\frac{k_1^2}{k_1'^2}\left\{1-2\frac{y}{a}\,k_1+k_1^2\right\}E_1+\left(\frac{y}{a}-k_1\right)k_1(K_1-E_1)\right] \tag{13}$$

$$H_r=A\,\frac{x}{y}\ \frac{\rho_1+\rho_2}{\rho_1\rho_2}\left[\frac{k_1^2}{k_1'^2}\,E_1-\frac{1}{2}(K_1-E_1)\right] \tag{14}$$

in which K_1 and E_1 are complete elliptic integrals to modulus

$$k_1=\frac{4y/a}{(\rho_1+\rho_2)^2}$$

and complimentary modulus

$$k_1'^2=\frac{4\rho_1\rho_2}{(\rho_1+\rho_2)^2}$$

These are not as simple as Russell's equations, but they may be expanded without difficulty. Of these expansions only those in powers of k_1^2 are given here

$$H_z=\frac{2\pi A}{\rho_1\rho_2(\rho_1+\rho_2)k_1'^2}\left[\left(1+\frac{k_1^2}{4}+\frac{k_1^4}{64}+\frac{k_1^6}{256}+\frac{25}{16{,}384}k_1^8+\frac{49}{65{,}536}k_1^{10}+\ldots\right)-\frac{3}{2}\frac{y}{a}k_1\left(1-\frac{k_1^2}{8}-\frac{k_1^4}{64}-\frac{5}{1{,}024}k_1^6-\frac{35}{16{,}384}k_1^8-\frac{147}{131{,}072}k_1^{11}-\ldots\right)\right] \tag{15}$$

$$H_r=\frac{3\pi A\frac{x}{a}k_1}{\rho_1\rho_2(\rho_1+\rho_2)k_1'^2}\left[1-\frac{k_1^2}{8}-\frac{k_1^4}{64}-\frac{5}{1{,}024}k_1^6-\frac{35}{16{,}384}k_1^8-\frac{147}{131{,}072}k_1^{10}-\ldots\right] \tag{16}$$

These give very accurate values up to about $k_1^2=1/4$, to which corresponds $k'^2=1/9$, so that they provide an overlap between formulas 5 to 8 and 9 to 12. Formulas 13 to 16 are believed to be new.

Routine Calculations of the Magnetic Field Components of a Circular Filament

The formulas listed by Dwight, together with those presented here, enable the magnetic field components of a circular filament to be calculated at all possible points. However, the number of formulas, their various ranges of convergence, and the number of geometrical parameters involved, tend to confuse the computer. A systematic procedure is desirable.

In the Russell equations 3 and 4 only two parameters appear, namely, ρ_1 and $k'^2=\rho_2^2/\rho_1^2$. The elliptic integrals depend upon the latter alone, and if tables of the elliptic integrals are at hand, the Russell equations provide a practical solution of the problem, without the necessity of investigating which of the series formulas is sufficiently convergent for the problem in question.

For numerical calculations using Russell's formulas tables of elliptic integrals based on k^2 or k'^2 as argument are especially convenient,[13] but for small values of k'^2 (points near the filament) these tables suffer from the usual difficulty due to the rapid increase of K with k. Interpolation is however rendered satisfactory if, instead of k'^2, log k'^2 is chosen as argument of the table. Table I has been calculated on this basis and suffices for the most precise work. The writer does not know of the existence of other tables based on this argument. This table is useful also for the case of a solenoid to be considered later. For many cases linear interpolation in the table will suffice, but for very precise work the second difference should be taken into account.

It is an advantage to use logarithms in the calculations. From the given coordinates, ρ_2^2 and ρ_1^2 and their ratio k'^2 are calculated, and from the logarithm of the latter the elliptic integrals are interpolated with a minimum of entries in the logarithm table. From the calculated values of H_z and H_r, the total magnetic intensity vector $\boldsymbol{H}$ and its direction θ with respect to the axis of the filament are found by the relations

$$\tan\theta=\frac{H_r}{H_z} \qquad \boldsymbol{H}=\frac{H_z}{\cos\theta} \tag{17}$$

Unfortunately, for the case of very distant points, the Russell formulas suffer from the disadvantage that the results are given by the small difference of nearly equal terms. For more precise work in such cases, series formulas 15 and 16 in terms of the modulus k_1 are recommended.

Example 1. For a circular filament with 10 centimeter radius, carrying a current 20 amperes, find the magnetic field components at the point $x=10$, $y=11$ centimeters.

Here $a=10$, $A=40/100=0.4$, $x/a=1$, $y/a=1.1$, $\rho_2^2=1.01$, $\rho_1^2=5.41$. Hence, log $\rho_2^2=0.0043214$, log $\rho_1^2=0.7331973$ and thus log $k'^2=9.2711241-10$. Interpolating in Table I for this value of log k'^2, there are found $E=1.16943$ and $(K-E)=1.11914$.

log $2(1-y/a)E=$ $n\bar{1}.3690042$
log ρ_2^2 $=$ 0.0043214
log difference $=$ $n\bar{1}.3646828$
$K-E$ $=$ 1.11914
minus difference $=$ -0.23157
Difference $=$ 0.88757
log Difference $=$ $\bar{1}.9482026$
1/2 log ρ_1 $=$ 0.3665986
$\bar{1}.5816040$
H_z $=$ $0.381595A$
$=$ 0.152638 gauss

The same example solved by the series formulas 9 and 11 give $H_z=0.381604A$ and $0.381591A$ respectively. For the radial component

$(2/\rho_2^2)E$ $=2.315703$
$(x/y)(K-E)=1.017400$
Difference $=1.298303$

and

H_r $=0.558184A$
$=0.223274$ gauss

By formula 10, $H_r=0.558180A$; by formula 12, $H_r=0.558183A$. Dwight's formula for this case gives $H_r=0.55846A$, but the value of $\mu^2=u^2/Dd$ is here too large for higher order terms to be neglected.

The calculation of the total magnetic field vector follows

log H_r $=\bar{1}.7467769$
log H_z $=\bar{1}.5816010$
log tan θ $=0.1651759$
log cos θ $=\bar{1}.7515563$
log $H_z/\cos\theta=\bar{1}.8300447$

or $\boldsymbol{H}=0.67615A=0.270460$ gauss, inclined to the filament axis by the angle $\theta=55$ degrees 38 minutes 31.7 seconds.

Example 2. In the case $x/a=10$ and $y/a=10$,

$\rho_2^2=181$ log $\rho_2^2=2.2576786$
$\rho_1^2=221$ log $\rho_1^2=2.3443923$
log $k'^2=\bar{1}.9132863$

and from Table I, $E=1.49710$ and $(K-E)=0.15306$.

$K-E$ $=$ 0.15306
$2(1-y/a)E/\rho_2^2=$ -0.14888
Difference $=$ 0.00418
H_z $=$ $0.0002812A$

The Russell formula is unfavorable, not only because of the smaller number of significant figures in the tabular value of $(K-E)$, but because of the near cancellation of terms.

By formula 15 log $k_1=\bar{2}.6978826$. In the series, terms in k_1^2 only have to be calculated.

First series $=1.000622$
Second series $=0.747892$
Difference $=0.252730$
$\therefore H_z=0.00028105_7A$ by equation 15
$=0.00028104_3A$ by equation 5
$=0.00028104_8A$ by equation 7

For the calculation of the radial component, the Russell formula gives

$[(2x/a)/\rho_2^2]E=0.165425$
$(x/y)(K-E)=0.15306$
Difference $=0.012365$

and

$H_r=0.0008318A$
$H_r=0.00083172\,A$ by equation 6
$H_r=0.00083171_9A$ by equation 8
$H_r=0.00083171_9A$ by equation 16

The total field intensity is $H=0.00087784A$, and $\theta=71$ degrees 19 minutes 43.2 seconds.

Magnetic Field Strength Due to a Current in a Thin Solenoid

Formulas for the magnetic field strength due to a current in a thin solenoid may be obtained by the integration of the formulas for the field components of a circular filament. If, in Figure 2, it is assumed that the winding density of the solenoid of radius a is n turns per centimeter of axial length, we may multiply a suitable expression for H_x or H_r, due to a circular filament, by $n\,dx$ and integrate between $x=x_1$ and $x=x_2$, with $x_2=x_1+x_0$, to obtain the value of H_x or H_r due to the solenoid at the point. The integrated expression for the value $x_1=0$ is zero, so that the basic case is that of a solenoid of length x with the point P in its end plane. That is, the field strength at point P in Figure 2 is the difference of the values due to two solenoids, each of radius a, one of length x_1 and the other of length x_2, the point P being in the end plane of both. As Dwight pointed out, this method of treatment has the advantage that the two values, which are to be subtracted, do not have to be calculated by the same formula, but each may be obtained separately by the most favorable formula from the standpoint of convergence.

Of the available series formulas for the circular filament, not all are easily integrable, and some do not yield simple series expressions.

Dwight's formulas 3 and 9, given on pages 275 and 278 of reference 6, are in fact especially favorable. In general, the problem of the solenoid may be treated more easily by other methods. The radial and axial components will be separately treated here.

Radial Component H_r of a Thin Solenoid

Let

H_{r0} = the radial component due to a circular filament
H_{rs} = the radial component at P (Figure 2) due to a thin solenoid of length x_0 and radius a
n = winding density of the solenoid
M_0 = the mutual inductance of two circular coaxial filaments of radii a and y_0 with a distance x between their planes

Then

$$H_{rs}=n\int_{x_1}^{x_2} H_r dx$$

Substituting from formula 2

$$H_{rs}=-\frac{n}{2\pi y}\int_{x_1}^{x_2}\frac{\partial M_0}{\partial x}dx$$

$$=-\frac{n}{2\pi y}\left[M_{0x_2}-M_{0x_1}\right] \qquad (18)$$

in which M_{0x_2} and M_{0x_1} are, respectively, the mutual inductances of pairs of circular filaments of radii a and y with distances between their planes of x_2 and x_1.

From formula 18 it is evident that the radial component at point P due to the solenoid of Figure 2 may be calculated from the difference of the mutual inductances of two pairs of coaxial circles, and these may be calculated individually by any favorable formula of the large number known.

Since Dwight's[6] formula 7 for H_{r0} was obtained by the differentiation of Havelock's formula for the mutual inductance of two coaxial circular filaments with respect to x, while his equation 9 for H_{rs} is the result of integrating equation 7 with respect to x, between the limits zero and x, formula 9, therefore, should be equivalent to Havelock's formula, except for the factor $n/2\pi y$ the limits x and zero having been substituted and the results subtracted.

This conclusion can be verified readily. There is an advantage, however, in using equation 18 as it stands, without introducing the limit zero. This procedure avoids the difficulty that for $y=a$ and $x=0$, in formula 9, the term $\log_e(16Dd/c^2)$ becomes infinite.

Routine calculations of H_{rs} are very simple if the mutual inductances in equation 18 are computed with the aid of existing tables.[14] See example 5.

Formulas for the Axial Component H_z, of a Thin Solenoid

For the calculation of the axial component due to the solenoid, conditions are not so simple. It does not seem feasible to integrate Russell's equation 3 with respect to x. Of the series formulas 5 to 12, only formula 11 seems to yield a valuable formula. This is a result equivalent to Dwight's formula 3 page 275 of reference 6. The axial component, however, may be obtained by the differentiation of a suitable mutual inductance formula.

We may write, from formula 1

$$H_{z0}=\frac{-1}{2\pi y}\frac{\partial M_0}{\partial y}$$

and from Figure 2.

$$H_{z0}=n\int_{x_1}^{x_2} H_{z0}\,dx=\frac{n}{2\pi y}\int_{x_1}^{x_2}\frac{\partial M_0}{\partial y}dx$$

$$=\frac{n}{2\pi y}\frac{\partial}{\partial y}\left[\int_{x_1}^{x_2} M_0\,dx\right]$$

But

$$n\int_{x_1}^{x_2} M_0 dx$$

is the mutual inductance M_{s0} of the solenoid and a coaxial circle passed through point P; this also may be written

$$M_{s0}=n\left[\int_0^{x_2} M_0\,dx-\int_0^{x_1} M_0\,dx\right]$$

in which each of the integrals represents the mutual inductance of a solenoid and coaxial circle in its end plane. Thus, in general

$$H_{zs}=\frac{1}{2\pi y}\left[\left(\frac{\partial M_{s0}}{\partial y}\right)_{x=x_2}-\left(\frac{\partial M_{s0}}{\partial y}\right)_{x=x_2}\right] \qquad (19)$$

Any available formula for the mutual inductance of a solenoid and a circle in its end plane may be used for the differentiations indicated in equation 19. Since, in general, differentiation is always possible, this is an especially valuable method of attack.

Only two series formulas for the mutual inductance of solenoid and coaxial circle are known. One of these, which is rapidly convergent for short solenoids and a circle near the solenoid, is given by Dwight as formula 21 on page 245 of reference 6.

Differentiating this with respect to y and using formula 1 leads to the same equation 3, page 275 of reference 6, which Dwight[5] found by integrating his formula 2* with respect to x. This gives a check of the method.

A second mutual inductance formula, due to Rosa,[16,17] may be simplified by the substitution $x^2=r^2-A^2$ to give Dwight's equation 22, page 246 of reference 6.

This formula applies, either with the radius of the solenoid larger than that of the circle, or the reverse case, provided only that in either case A in the formula is understood to be the larger radius. Accordingly, in carrying out the differentiation of this expression with respect to y, the result is different, according as y is smaller or greater than a.

For the case $y<a$, points near the axis

$$H_{zs}=\frac{2\pi nIx}{10r}\left[1+\frac{3}{4}\alpha^2\rho^4-\frac{15}{16}\alpha^4\rho^6\xi_2+\right.$$
$$\frac{35}{32}\alpha^6\rho^8\xi_4-\frac{315}{256}\alpha^8\rho^{10}\xi_6+$$
$$\left.\frac{693}{512}\alpha^{10}\rho^{12}\xi_8-\frac{3{,}003}{2{,}048}\alpha^{12}\rho^{14}\xi_{10}+\ldots\right] \qquad (20)$$

where

$$\alpha=y/a$$

$$\rho^2=\frac{a^2}{x^2+a^2}=\frac{a^2}{r^2}$$

$$\xi_2=1-\frac{7}{4}\rho^2$$

$$\xi_4=1-\frac{9}{2}\rho^2+\frac{33}{8}\rho^4$$

$$\xi_6=1-\frac{33}{4}\rho^2+\frac{143}{8}\rho^4-\frac{715}{64}\rho^6$$

$$\xi_8=1-13\rho^2+\frac{195}{4}\rho^4-\frac{1{,}105}{16}\rho^6+\frac{4{,}199}{128}\rho^8$$

$$\xi_{10}=1-\frac{75}{4}\rho^2+\frac{425}{4}\rho^4-\frac{8{,}075}{32}\rho^6+$$
$$\frac{33{,}915}{128}\rho^8-\frac{52{,}003}{512}\rho^{10}$$

The ξ functions oscillate between plus one and a negative maximum not as great as one unit. Making use of the relation $x^2/r^2=1-a^2/r^2$, and the known expressions for $P_n'(\mu)$, it is easy to show that formula 20 is equivalent to Dwight's formula 42 on page 289 of reference 6, for the case that $t=0$. This latter expression is easy to use, if tables of $P_n'(\mu)$ are at hand. Otherwise formula 20 is compact and not difficult to calculate.

If $y>a$, points distant from the axis, differentiation of the Rosa-Dwight expression for M_{s0} results in the following simple formula, after having used the relation $y^2/r^2=1-x^2/r^2$

---

* This formula (2) should have $-c/d$ instead of $+c/d$ in the last line.

$$H_{zs}=-\frac{\pi nIa^2x}{10r^3}\left[1-\frac{3}{4}\frac{a^2}{r^2}\frac{P_3(x/r)}{x/r}+\frac{5}{8}\frac{a^4}{r_4}\frac{P_5(x/r)}{x/r}-\frac{35}{64}\frac{a^6}{r^6}\frac{P_7(x/r)}{x/r}+\ldots\right] \tag{21}$$

with $r^2=x^2+y^2$. The general term is

$$\frac{(-1)^{2n+1}3\cdot5\cdot7\ldots(2n+1)}{4\cdot6\cdot8\ldots(2n+2)}\frac{P_{2n+1}(x/r)}{x/r}\cdot\frac{a^{2n}}{r^{2n}}$$

in which P_{2n+1} is the zonal harmonic.

This formula is seen to be the same as Dwight's formula 39 page 288 of reference 6, for the case $t=0$. If tables of zonal harmonics are available, this is a very convenient formula for computation, in cases where the convergence is sufficiently rapid.

Unfortunately, these existing series formulas for H_{zs} do not overlap sufficiently well to allow very precise calculations in certain cases. An expression in elliptic integrals, which will apply in all cases, is much to be desired. The Jones-Campbell[18,19] elliptic integral formula for the mutual inductance of a solenoid and coaxial circular filament in its end plane furnishes this solution. The differentiation of this expression with respect to y is straightforward, but the algebraic manipulation is far from simple. In the course of this work, the writer discovered that Campbell[19] had made this differentiation, but for a different purpose, in his study of the most favorable dimensions for his standard of mutual inductance. No details of the work are supplied there.

The result given here although different in form, checks Campbell's differentiation completely. The result is

$$H_{zs}=\frac{nI}{10}\left[\frac{4ax}{r_1(a+y)}\cdot K\mp 2\psi\right] \tag{22}$$

$$=\frac{nI}{10}\left[\frac{4x/a}{\rho_1(1+y/a)}\cdot K\mp 2\psi\right] \tag{22a}$$

The upper sign is to be used when $y<a$, and the lower sign for $y>a$.* The function ψ is given by

$$\psi=KE'-(K-E)F'-\frac{\pi}{2} \tag{23}$$

in which K and E are complete elliptic integrals whose modulus k and complementary modulus k' are given by $k^2=4ay/r_1^2$ and $k'^2=\rho_2^2/\rho_1^2$, just as equations 3(a) and 4(a) for the circular filament. Note that here, however, x is the length of the solenoid. F' and E' are incomplete elliptic integrals with modulus equal to k' and amplitude $\beta=\sin^{-1} c'/k'$ with $c'^2=(y-a)^2/(y+a)^2$.

Routine Calculations for the Thin Solenoid

The complete elliptic integral K in equation 22 can be obtained from Table I for the given value of $\log_{10}k'^2$. Values of Ψ, which will be recognized as involving an elliptic integral of the third kind, give especial difficulty, since it depends not only on the modulus but on the parameter $c^2=1-c'^2$. Values of Ψ may be calculated from the defining equation 23, using Legendre's table of incomplete integrals[20] or the tables of Jahnke and Emde,[21] but in general the interpolations are tedious and time consuming. The tables presented here have the advantage that the interpolations necessary do not enter into the principal terms.

Writing $\Psi=(-\pi/2)+\beta+D$, the quantity $D=f_0k'^2\sin2\beta$ may be calculated from values of f_0 tabulated with $\log_{10}k'^2$ and β as arguments in Table II. The value of β in radians may be taken from the usual conversion table common in collections of formulas.

For values of k'^2 nearly unity it is better to write $\Psi=(-\pi/2)(1-p\sin\beta)$ and then to obtain values of $\log p$ from Table III for the given arguments $\log k'^2$ and β. In computing Table II a series expression for ψ in powers of k'^2, derived from known series[18] for F' and E' was used. For larger values of k'^2 the Legendre tables had to be used. For the calculation of $\log p$, a development for ψ in terms of

---

* For the special case $y=a$ in equation 22, $\psi=-\pi/2$, whatever the length x of the solenoid. Therefore, in the calculation of the axial component at the point P, the term ψ is the same both for the calculation for $x=x_1$ and $x=x_2$, and cancels in the difference. The axial component in this case is therefore given by the difference of the terms in K in equation 22 as calculated for the two values of x. In the basic formula for the point $y=a$ in the end plane, the point is in contact with the end of the winding, and the axial component is indeterminate. This difficulty does not arise for a winding of finite thickness.

Table II. Values of f_0 as Function of k'^2 and β

arithmetico-geometric series was employed.

Example 3. To find the axial component H_{xs} due to a solenoid of radius $a=5$ centimeters, length $x=25$ centimeters, at a point in the end plane for which $y=20$.

Here

$r_2^2=(15)^2+(25)^2=850$
$r_1^2=(25)^2+(25)^2=1{,}250$
$c'^2=\left(\frac{15}{25}\right)^2$
$4ax=500$
$\log c'^2 \quad =\bar{1}.5563025$
$\log k'^2 \quad =\bar{1}.8325089$
$\log \sin \beta=\bar{1}.8618968$
$\beta=46$ degrees 41 minutes 10.1 seconds = 0.81483 radians
β = 46.6861 degrees
$\log \sin 2\beta=\bar{1}.99925$

From Table I, $K=1.72578$, and from Table II $f_0=0.35056$, while Table III gives $\log p=\bar{1}.96430$

$f_0k'^2 \sin 2\beta = 0.23797$
$\beta = \underline{0.81483}$
Sum $= 1.05280$
$-\pi/2 = \underline{-1.57080}$
$\psi = -0.51800$

$(\pi/2)p \sin \beta = 1.05274$
$-\pi/2 = \underline{-1.57080}$
$\psi = -0.51806$

A very accurate calculation of Ψ using arithmetico-geometric-mean series gave -0.518017. Using this value

$2\psi = -1.036034$
Term in $K = \underline{0.976249}$
Sum $= -0.059785$
$H_{xs} = -0.059785nI/10$

This result may be checked by formula 21, that is, Dwight's formula 39

$r^2=x^2+y^2=1.025$
$x/r=0.78087$

$$\frac{P_3(x/r)}{x/r}=0.0244$$

$$\frac{P_5(x/r)}{x/r}=-0.5325$$

$$\frac{P_7(x/r)}{x/r}=-0.2080$$

The terms in the series are $(1-0.000446-0.000198+0.000002)=0.999358$, and $H_{xs}=-0.0597950nI/10$. The negative sign signifies that the field is opposed in direction to that at points on the axis.

Example 4. For the case $a=5, x=50$, and $y=2$. $r_2^2=2509$, $\log c'^2=\bar{1}.2640464$, $4ax=1000$ $r_1^2=2549$, $\log k'^2=\bar{1}.9931309$, $K=1.57701$, $\beta=25$ degrees 35 minutes 34.5 seconds = 25.5929 degrees.

From Table III, $\log p=\bar{1}.99829$, $\psi=-0.89492$. A very accurate calculation of ψ gives -0.8949208.

First term $= 4.462226$
$2\psi = -1.789842$

Difference gives $H_{xs}=6.252068nI/10$. Using formula 20 $r^2=25+2{,}500=2525$, $\xi_2=0.98267$, and higher order terms are negligible. $H_{xs}=2\pi x/r(1.0000118)nI/10$ $6.252077nI/10$.

Example 5. A good illustration of the usefulness of the formulas and tables here developed is furnished by a study of Campbell's form of mutual inductance standard,[19] Figure 3. Two equal coils of radii 10 centimeters and axial lengths 5 centimeters are placed coaxial with a separation between their nearer ends of 10 centimeters. Each is wound with 10 turns per centimeter that is, a total of 50 turns. In the median plane is placed a coaxial circular coil with 1,000 turns, wound in a square cross section one centimeter on a side. The mean radius of this coil, $y=14.5$ centimeters was chosen so that the turns of this secondary lie in a region of nearly zero magnetic field intensity. Under this condition, the mutual inductance of the secondary on the two primary coils in series is nearly the same as though all the secondary turns were concentrated at the center of the cross section, point P.

By symmetry, with the two primaries aiding magnetically, their radial components cancel, and the resultant field at P is twice the axial component due to one. The axial component produced by each coil is equal to the difference of the values which would be produced by a solenoid 10 centimeters long and one 5 centimeters long with the point P in the end plane of each. These values are, respectively, $-6.6034I/10$ and $-6.6523I/10$, giving a resultant of $0.0489I/10$ and, for both coils, $H_{xs}=+0.0978I/10$. This case is unfavorable for the use of formulas 21 and Dwight's formula 3. For $x=10$, formula 21 gives $-6.5998I/10$ and for $x=5$, formula 3 gives $-6.472I/10$.

Repeating the calculation of H_{xs} for $y=14.6$, the resultant field is $-0.0210I/10$, which indicates that H_{xs} becomes zero at $y \cong 14.58$, which agrees with Campbell's estimate of 14.6.

It is to be noted that the calculation of H_{xs} using formula 22 depends on data useful also for calculating the mutual inductance by Campbell's formula.[19] Multiplying the mutual inductance of the turn at the center of the cross section by 1,000 gives a value of 9.17588 millihenrys, uncorrected for the effect of a finite cross section.

The mutual inductance per turn of the secondary is a maximum for a turn at the point of zero magnetic field intensity, but the maximum is very flat. The value for

Table III. Values of $\log_{10} p$ as Function of $\log_{10} k'^2$ and β

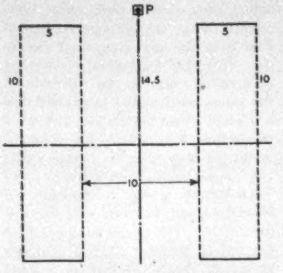

Figure 3. Arrangement of Campbell-type of mutual inductance standard

$y=14.6$ is only 30 parts in a million greater than that for $y=14.5$. The value, for given y, is a minimum in the median plane, as far as axial displacements are concerned, but this minimum also is very flat.

It is safe to assume that derivatives of M, with respect to either co-ordinate, of order higher than the second are negligible.

The value of the mutual inductance, taking into account the effect of a finite rectangular cross section of radial dimension c and axial dimension b, is, then

$$M_{corr.}=N_2\left[M_P+\frac{b^2}{24}\left.\frac{\partial^2 M}{\partial x^2}\right|_P+\frac{c^2}{24}\left.\frac{\partial^2 M}{\partial y^2}\right|_P\right] \tag{24}$$

or, making use of formulas 1 and 2

$$M_{corr.}=N_2\left[M_P-\frac{2\pi b^2 y}{24}\left.\frac{\partial H_{rs}}{\partial x}\right|_P+\frac{2\pi c^2}{24}\left(H_{zs}+y\frac{\partial H_{zs}}{\partial y}\right)_P\right] \tag{25}$$

The subscript P designates values at the central point P.

Campbell[19] solved for this correction by a quadrature formula derived from formula 24, which requires the calculation of M at points located at the centers of the sides of the rectangle, as well as at P. With $y=14.5$ for point P, $b=1$ and $c=1$, the correction is 12 parts in a million, the corrected value being larger than the uncorrected.

To apply formula 25, we already have from the calculations of H_{zs} at $y=14.5$ and 14.6, the derivative

$$\left.\frac{\partial H_{zs}}{\partial y}\right|_P=-1.188$$

We need the value

$$\left.\frac{\partial H_{rs}}{\partial x}\right|_P$$

To obtain this, we may calculate H_{rs} for $y=14.5$ and a displacement of $\Delta x=0.1$ centimeter. The required mutual inductances in formula 18 are for circles of radii 10 and 14.5, and with the distances between their planes to be shown. These mutual inductances will here be calculated from the formula $f\sqrt{ay}$ in abhenries, the values of f being interpolated from tables.[14,15]

Left hand coil

$x_2=9.9$
$r_2^2=(4.5)^2+(9.9)^2=118.26$
$r_1^2=(24.5)^2+(9.9)^2=698.26$
$k'^2=0.1693639$
$1000f=5.703$

$x_1=4.9$
$r_2^2=(4.5)^2+(4.9)^2=44.26$
$r_1^2=(24.5)^2+(4.9)^2=624.26$
$k'^2=0.0708999$
$1000f=10.111$

$$H_{rs}\ left=\frac{10\sqrt{145}(10.111-5.703)}{2\pi(14.5)}$$
$$=5.8260 \text{ radially outward}$$

Right hand coil

$x_2=10.1$	$x_1=5.1$
$r_2^2=122.26$	$r_2^2=46.26$
$r_1^2=702.26$	$r_1^2=626.26$
$k'^2=0.1740951$	$k'^2=0.073867$
$1{,}000f=5.574$	$1{,}000f=9.891$

$$H_{rs}\ right=\frac{10\sqrt{145}(9.891-5.574)}{2\pi(14.5)}$$
$$=5.7058 \text{ radially inward}$$

The resultant is, therefore, $5.8260-5.7058=0.1202$, radially away from the axis, and since H_{rs} at P is equal to zero, and $\Delta x=-0.1$,

$$\left.\frac{\partial H_{rs}}{\partial x}\right|_P=-1.202$$

This is checked by Dwight's formula 9. It is possible also to calculate this derivative by the formula

$$\left.\frac{\partial H_{rs}}{\partial x}\right|_P=2n\left(\underset{x=x_2}{H_{r0}}-\underset{x=x_1}{H_{r0}}\right) \tag{26}$$

obtained by the use of formula 1. This calculation thus is made to depend upon the radial components of circular filaments, using formula 4 and Table I. By this method only two values of H_{r0} have to be calculated, and the derivative so found applies strictly to point P if y is taken equal to 14.5 and the two values of x are taken as $x_2=10$ and $x_1=5$. Using this method there is found $(\partial H_{rs}/\partial x)_P=-1.2158$.

Calculating by formula 25 with

$$\left.\frac{\partial H_{rs}}{\partial y}\right|_P=-1.184$$

$$\left.\frac{\partial H_{rs}}{\partial x}\right|_P=-1.216$$

$H_{zs}=0.0978$

$M_p=9176$ abhenries

the correction factor is found to be 1.0000156, thus agreeing well with the value 1.000012 found by the quadrature formula.

Influence of Finite Cross Section on Calculation of H_z and H_r

The formulas of this paper refer, strictly, only to circular filaments and cylindrical current sheets. The correction of the values so calculated, to apply, respectively, to a circular coil of rectangular cross section and to a solenoid of finite thickness, have been thoroughly treated by Dwight in pages 292–6 and 276–280 of reference 6.* As would be expected, the corrections are greater, the larger the cross-sectional dimensions compared with the other co-ordinates involved, and the nearer, relatively, the point is situated to the winding. However, except in unfavorable cases and for calculations where a moderate accuracy suffices, the values calculated for a circular coil may be made assuming its turns to be concentrated at the middle of its cross section, and for solenoids with the assumption of its equivalence with a thin solenoid having a radius equal to the mean radius of the actual coil.

* A more general procedure is to replace the coil by its equivalent circular filament as proposed by Lyle.[22,23] With n filaments, assuming N/n turns associated with each, the contribution of each to the magnetic field may be calculated by the Russell formulas. The number n will be larger, the larger the cross section. This procedure is to be recommended for solenoids when point P is very distant.

No Discussion

Nonharmonic Oscillations as Caused by Magnetic Saturation

REINHOLD RÜDENBERG
MEMBER AIEE

MANY of the conventional methods of investigating free and forced oscillations in nonlinear circuits tend to approximate the problem in one way or another in order to attain a suitable analytical solution. A number of different approaches have been proposed as: limitation to the amplitudes of oscillation without concern about the wave shape; omission of higher order terms in a series expansion difficult to evaluate; approximation of the magnetic characteristic by a closed mathematical function; neglecting the transient part of the solution; decomposition of the characteristic into several linear portions; linearization by other analytical or geometrical approximations.

Valuable results have been derived from such analyses, for example the facts that no regular resonance effects can occur under sinusoidal excitation, that under equal over-all conditions there may develop more than one stable performance of the electric circuit, usually an ordinary state of low current and an extraordinary state of high current, and that particularly in the latter state intense higher harmonics and also subharmonics may occur.

Our present aim is to investigate in detail the effect on the wave shape* within every cycle, produced by the nonlinear characteristic of circuits containing capacitance and saturated inductance. In many examples of actual electric systems one or the other element has a curved characteristic and this always can be reduced to the analysis which we will develop. Usually, the characteristic is given graphically from experimental data, and this fact suggests deducing the solution also by some type of graphical evaluation. A rigorous method can be derived which for natural oscillations constitutes a closed formulation based on quadratures, whereas for forced oscillations a step-by-step method will be developed.

All of the methods discussed here† may be transferred easily to mechanical or other types of oscillations as it will be shown by one example.

Distortion of Natural Oscillations

We consider at first the electromagnetic oscillations of a saturated flux Φ, the exciting coil of which is connected to a capacitance C as indicated in Figure 1. The magnetic characteristic is shown in Figure 2, however, instead of flux Φ and exciting current i there are taken as variables the magnetic induction B and the linear current density A. These more specific magnitudes are correlated to Φ and i by the cross-section a of the magnetic circuit, its length l, and the number of turns N as

$$B=\frac{\Phi}{a};\qquad A=\frac{Ni}{l} \tag{1}$$

The differential equation for the natural oscillations is, in the absence of ohmic resistance

$$N\frac{d\Phi}{dt}+\frac{1}{C}\int i\,dt=0 \tag{2}$$

which changes by use of equation 1 into

$$aN\frac{dB}{dt}+\frac{l}{NC}\int A\,dt=0 \tag{3}$$

If we now introduce for abbreviation the parameter

$$\tau=\sqrt{C\frac{a}{l}N^2}=\sqrt{C\Lambda} \tag{4}$$

which we will term the intrinsic time of the device, equation 3 yields, after differentiation, the simple differential equation

$$\frac{d^2B}{dt^2}+\frac{A}{\tau^2}=0 \tag{5}$$

This characteristic equation which determines the performance of the electromagnetic circuit contains only two parameters, namely the intrinsic time τ which is a constant of the system, and the magnetic characteristic, as shown in

Special Letter Symbols

A = linear current density
b = harmonic induction amplitude
β = virtual permeability
ϵ = voltage ratio
ϑ = numerical time
Λ = self-inductance in air
ρ = resistance ratio
τ = intrinsic time

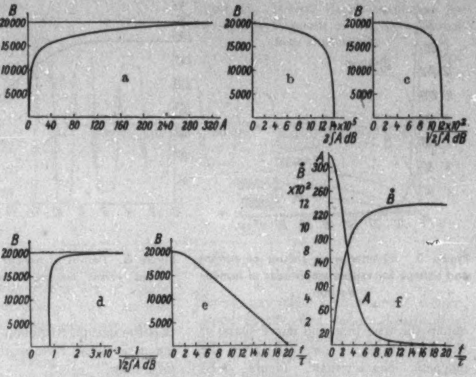

Figure 3. Successive integration of magnetic characteristic yielding the shape of natural oscillations

Figure 2, which is a graphically given function, analytically expressed either as $B(A)$ or as $A(B)$. According to equation 4 the intrinsic time is determined solely by the magnitudes of the capacitance C and a self-inductance Λ, the latter representing the inductance of the exciting coil if the iron of the magnetic circuit were replaced by air. Hence, τ appears as the natural period of an air flux, expressed in units of 2π seconds.

Any additional magnetic flux, either in leakage paths parallel to the steel yoke or in a constant inductance in series with the electric elements, can be considered by shearing the abscissa axis of Figure 2 into the dashed position. On the other hand, any air gap in the magnetic circuit or any constant inductance in parallel to the electric elements can be considered by shearing the ordinate axis of Figure 2 into the dashed position. Hence, the performance of a wide variety of saturated electromagnetic circuits can be described by the same differential equation 5.

This equation can be solved by separation of the variables. At first we multiply the equation by the derivative $\dot{B}=dB/dt$, yielding

$$\dot{B}\frac{dB}{dt}+\frac{d\dot{B}}{dt}\cdot\frac{A}{\tau^2}=0 \tag{6}$$

or, rewritten after cancellation of dt

$$\dot{B}d\dot{B}+\frac{1}{\tau^2}AdB=0 \tag{7}$$

This yields, when integrated

$$\frac{\dot{B}^2}{2}+\frac{1}{\tau^2}\int_{B_0}^{B}AdB=0 \tag{8}$$

The integration in the second term may be performed graphically by use of the characteristic in Figure 2, and the lower limit must be chosen according to the initial conditions. A continuous change of the upper limit gives directly the integral curve. Hereby the derivative

$$\frac{dB}{dt}=\dot{B}=\sqrt{-\frac{2}{\tau^2}\int AdB} \tag{9}$$

is graphically determined as function of B alone. A further integration after separation of the variables yields the elapsed time as

$$t=\tau\int\frac{dB}{\sqrt{-2\int AdB}} \tag{10}$$

This integral also can be evaluated rigorously. We may draw the reciprocal curve of equation 9 and integrate it with respect to B. Or, we may plot the curve from consecutive elements dB/dt determined from equation 9. We will denote the integral of equation 10, equal to the ratio t/τ as the numerical time of oscillation. It depends solely on the shape of the effective characteristic, whereas all constant parameters of the system are comprised in the intrinsic time τ. After having found the correlation of induction B and time t, we can easily return by use of equation 1 to current i and voltage e, yielding

$$i=\frac{l}{N}A;\quad e=N\frac{d\Phi}{dt}=aN\frac{dB}{dt} \tag{11}$$

wherein the last derivative is already expressed by equation 9.

Let us apply equation 10 analytically to the simple case of a linear characteristic, as present in Figure 2 in the neighborhood of the origin. Here B is proportional to A, namely

$$B=\mu A \tag{12}$$

wherein μ is the initial permeability of the electromagnetic system. This gives for equation 9

$$\sqrt{-2\int AdB}=\frac{j}{\sqrt{\mu}}B \tag{13}$$

and with use of equation 10

$$t=\tau\frac{\sqrt{\mu}}{j}\ln\left(\frac{B}{B_0}\right) \tag{14}$$

After inverting this expression and replacing the exponential function of complex argument by its trigonometric equivalent this yields

$$B=B_0\cos\left(\frac{t}{\tau\sqrt{\mu}}\right) \tag{15}$$

Thus, the intrinsic time τ together with the square root of the permeability determine the period of oscillation which is, with use of equation 4

$$T=2\pi\tau\sqrt{\mu}=2\pi\tau\sqrt{\mu\Lambda C}, \tag{16}$$

Herein $\mu\Lambda$ expresses the self-inductance of the iron circuit. The period of oscillation is independent of the amplitude B_0 of the oscillation as long as the linear part of the characteristic is not exceeded and μ is a true constant.

For an actual characteristic of the iron, as curved by saturation, Figure 3 presents the procedure to be taken in order to

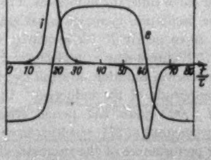

Figure 4. Wave shapes of current and voltage of saturated natural oscillations

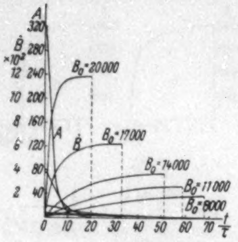

Figure 5. Quarter wave shapes of current and voltage for various amplitudes of iron induction

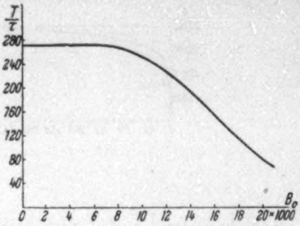

Figure 6. Period of natural electric oscillations versus maximum iron induction

obtain the true time and curve shape of the oscillations. Figure 3(A) gives the magnetic characteristic. Figure 3(B) shows the integral curve when starting at 20,000 gauss. The square root of this curve is taken in Figure 3(C). The reciprocal curve is shown in Figure 3(D) and this is integrated in Figure 3(E). The latter curve gives directly the correlation of time and magnetic induction and we see that the flux will decrease nearly linearly with time. Now we can correlate to each time, via the induction B, the current expressed by A from the original characteristic, and the voltage expressed by dB/dt from the abscissa of Figure 3(C), both as determined by equations 9 and 11. This is shown in Figure 3(F). Because of the complete symmetry, the curves are derived in Figure 3 for a quarter of a cycle only. From the last diagram the curves of current and voltage are plotted in Figure 4 for an entire cycle. The current has high peaks, the voltage very flat tops. The numerical period of oscillation evaluates to 80, whereas the same oscillatory circuit without iron would give only 2π, and both e and i would be sinusoidal.

Figure 5 shows the result of similar evaluations for smaller amplitudes B_0 than 20,000 gauss. Here also, only one-quarter of each cycle is shown for A and dB/dt representing current and voltage. We see that with decreasing amplitude the peaked and flat curves gradually lose their marked shape and approach for small oscillations a sine or cosine change. At the same time, the numerical duration of the oscillation increases considerably, from 20 to nearly 70 for a quarter of a cycle. Figure 6 shows the dependence of the numerical duration of a full cycle on the amplitude of the induction. Up to about 7,000 gauss the period remains nearly constant at 271, resulting from the linear performance of the magnetic characteristic. With further increasing amplitude the period decreases rapidly so that the natural frequency of the electromagnetic circuit rises greatly with higher saturation.

We see from this investigation that the natural oscillations of a magnetically saturated oscillatory circuit remain harmonic and have constant natural frequency only at small amplitudes. However, with increasing amplitude the curve shape of the oscillations becomes more and more distorted and simultaneously the natural frequency increases. These two properties, distorted curve shape and dependence of the natural frequency on the amplitude, are characteristic qualities of any nonharmonic oscillations.

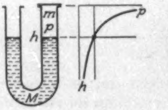

Figure 7. Oscillations of a gas volume in a liquid subjected to adiabatic compression

As a second example, let us investigate adiabatic oscillations of a gas bubble as they may occur in oil circuit breakers. We simplify the problem by considering the linear oscillation of a cylindrical gas volume v against a column of liquid mass M included in the same U-shaped guiding tube, as in Figure 7. Any motion of the level h produces a change in the pressure p on the surface area a between gas and liquid. The equilibrium of the forces on the liquid gives the differential equation

$$M\frac{d^2h}{dt^2}+ap(h)=0 \tag{17}$$

Introducing the specific volume v of the gas instead of the level h by

$$a\,dh=m\,dv \tag{18}$$

wherein m designates the mass of the gas, equation 17 yields

$$\frac{Mm}{a}\frac{d^2v}{dt^2}+ap(v)=0 \tag{19}$$

If we define the intrinsic time of this problem as

$$\tau=\frac{\sqrt{Mm}}{a} \tag{20}$$

we obtain the differential equation

$$\frac{d^2v}{dt^2}+\frac{p(v)}{\tau^2}=0 \tag{21}$$

This is of identical form to equation 5. Here, the intrinsic time depends on the product of the oscillating masses of liquid and gas related to their contacting area. Essentially, this is determined by the geometric mean length of the gas and liquid columns.

By analogy with equation 10 the solution of this problem is given by

$$t=\tau\int\frac{dv}{\sqrt{-2\int p\,dv}} \tag{22}$$

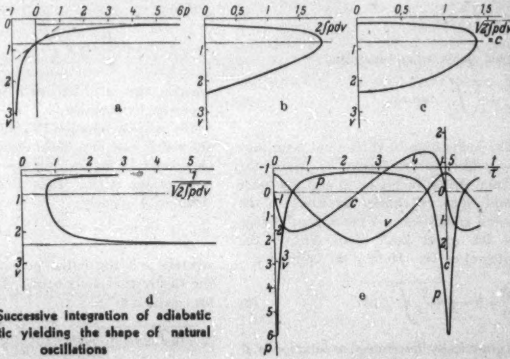

Figure 8. Successive integration of adiabatic characteristic yielding the shape of natural oscillations

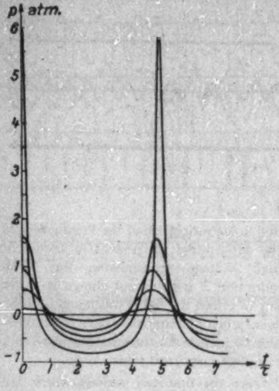

Figure 9. Wave shapes of gas pressure for various amplitudes of oscillation

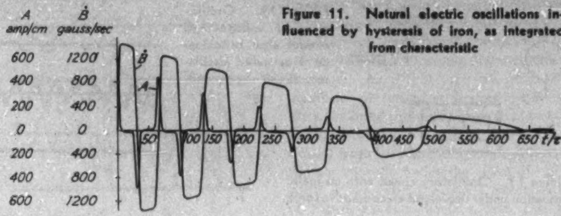

Figure 11. Natural electric oscillations influenced by hysteresis of iron, as integrated from characteristic

In Figure 8 the integration of the adiabatic pressure-volume curve of Figure 8(A) is carried out according to the same scheme as used in Figure 3. The integration results immediately in the curve of the gas volume v against time as shown in Figure 8(E), giving at the same time the level of the liquid column, see Figure 7. By transfer of the correlated values of pressure p from Figure 8(A) and velocity c from Figure 8(C), we obtain the various curves as plotted in Figure 8(E). We see that all the curves are unsymmetrical with respect to their mean axes and that the pressure curve forms a sharp positive peak and a flat negative saddle. This means that the oscillating liquid, by compression of the gas, will be very suddenly reflected as seen from the break in the v-curve, and this results from the gas pressure which increases very rapidly with decreasing volume causing also a nearly instantaneous change of the velocity.

The evaluation in Figure 8 is related to an initial pressure of 6 atmospheres. For some smaller amplitudes, the pressure oscillations are shown in Figure 9. We see that only small oscillations of the order of 1/10 atmosphere are of nearly sinusoidal shape, whereas large fluctuations of pressure produce very steep peaks.

The natural period of the oscillations is dependent only slightly on the amplitude, as seen from Figure 10. Although with larger fluctuations the duration of the excess pressure decreases, the period of suction increases and the sum changes slightly. Hence, such adiabatic pressure oscillations behave nearly isochronously.

If hysteresis is present in the magnetization curve, its ascending and descending branches must be distinguished in the evaluation of equation 10. This is done in Figure 11. Since now the initial energy is gradually dissipated by the hysteresis loss, a decay occurs and thus the oscillations pass through various wave shapes, as plotted in Figure 5. In Figure 12, an actual oscillogram of voltage and current of such an oscillation is shown which very nearly repeats the pattern of Figure 11, except that the damping is greater because of the additional losses in the ohmic resistance. In both these last figures the period of oscillation increases substantially during the decay up to a multiple of the initial value.

Transient Forced Oscillations

If the oscillatory circuit with magnetic saturation is fed by an external voltage $e(t)$ as in Figure 13, the complete circuit equation including the ohmic resistance, which we will no longer neglect, is

$$N\frac{d\Phi}{dt}+Ri+\frac{1}{C}\int i\,dt=e(t) \tag{23}$$

Herein, any effect of constant L is contained in the first term. Substituting again the specific values A and B for i and Φ as in equation 1, and the intrinsic time τ as in equation 4, we obtain

$$\tau\frac{dB}{dt}+\frac{RC}{\tau}A+\frac{1}{\tau}\int A\,dt=\frac{\tau}{aN}e(t) \tag{24}$$

If we now introduce abbreviations for the resistance factor and for the impressed electromotive force, namely

$$\rho=\frac{RC}{\tau}=\frac{R}{\sqrt{\Lambda/C}};\quad \epsilon(t)=\frac{\tau}{aN}e(t)=\sqrt{\frac{C}{al}}\quad e(t) \tag{25}$$

and designate the numerical time as ratio of elapsed time to intrinsic time by

$$\vartheta=\frac{t}{\tau} \tag{26}$$

equation 24 reduces to

$$\frac{dB}{d\vartheta}+\rho A+\int A\,d\vartheta=\epsilon(\vartheta) \tag{27}$$

This formulation comprises all the possible cases of saturated oscillations although it contains only four parameters. These are: the values of the constant τ and of the function $B(A)$ as formerly considered and defining the intrinsic time and the magnetic characteristic of the iron and air fluxes; and the new parameters of equation 25, namely the resistance ratio ρ designating the ohmic resistance as related to the oscillation resistance of the air-inductance, and $\epsilon(t)$ as the impressed voltage $e(t)$ related to a few

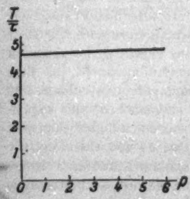

Figure 10 (left). Period of natural pressure oscillations versus maximum pressure

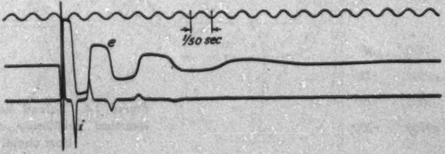
Figure 12 (right). Oscillogram of actual oscillation as influenced by resistance and hysteresis



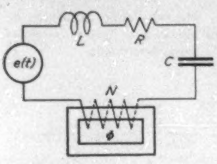


Figure 13. Oscillatory circuit with magnetic saturation under impressed electromotive force

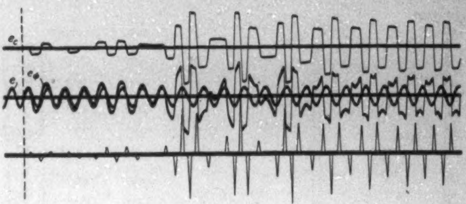

Figure 15. Oscillogram of voltages and current after switching-on a saturated oscillatory circuit at zero voltage

basic constants of the circuit. Thus, in equation 27 the first term is essentially determined by the shape of the magnetic characteristic, the second term by the value of the ohmic resistance, the third term by the performance of the capacitance, and the term on the right-hand side by the impressed voltage. Depending on the values of the parameters, the solution of equation 27 may have very different shapes. No assumption has been made about the curve $B(A)$ and thus, any actual form of the effective magnetic characteristic may be used for the evaluation.

If the elements of the circuit should not be connected in series, as in Figure 13, but in parallel, a formulation very similar to equation 27 can be derived. However, the second term will be $\rho' B$ rather than ρA and the resistance coefficient will be inverted to $\rho' = \tau/RC$.

For impressed direct voltage suddenly changing with time the transient performance can be found relatively simply because ϵ is constant before and after the jump. Hence, the perturbation term on the right-hand side of equation 27 has no further influence and the change in the deviations of B and A from the new steady state result from the left-hand side alone. This side, however, departs from equation 5 only by the resistance term ρA which can be handled during the integration as a correction. Therefore, oscillations will occur which are very similar in character to Figures 11 and 12, although they may be unsymmetrical in plus and minus values.

More interesting is the solution for alternating voltage. For the purpose of evaluation we rewrite equation 27 as

$$\frac{dB}{d\vartheta} = \epsilon(\vartheta) - \rho A - \int A\, d\vartheta \qquad (28)$$

Then we see that the change of the induction B with time is given in the first place by the impressed voltage, from which however, the resistance drop and the capacitive term must be deducted. The former is usually small, the latter, as an integral over time, also can be accurately obtained simultaneously with the development of the left-hand side. Figure 14 shows the curves for the inductive voltage $dB/d\vartheta$, the current A, and the capacitive voltage $\int A d\vartheta$, as derived in step-by-step construction from the impressed sinusoidal voltage $\epsilon(\vartheta)$ which suddenly is switched on. The graph is based on a circuit containing a moderately saturated transformer coil, a linear inductance in series, and some resistance of the conductors to the capacitance, as present in an actual high voltage transmission line. The induction B itself is not shown in order not to crowd the figure too much. However, when plotting the curve it is advisable to include all the variables used in a complete numerical table.

Over the first ten periods which are indicated in Figure 14 by dashed lines not a single cycle resembles any other. The phase angle of the voltage at the instant of switching is taken as zero and therefore an inrush current should be expected. However, by effect of the saturation such a peaked current develops gradually with large and irregular fluctuations of its amplitudes. By no means are these amplitudes alternating throughout. In many cycles two unidirectional amplitudes of current follow each other. No regular repetition of the phenomena is discernible during the time covered by Figure 14. The inductive voltage $dB/d\vartheta$ is fairly similar to the impressed voltage $\epsilon(\vartheta)$, although many irregular deviations are present. The capacitive voltage $\int A d\vartheta$ however, shows a very different performance consisting mostly of trapezoidal shapes with flat tops, the latter frequently extending over more than a full cycle. Thus, in contrast to any harmonic performance these curves indicate the occurrence of considerable nonharmonic currents and voltages, containing periods very different from that of the impressed voltage.

In Figures 15 and 16 some oscillograms are shown, taken when suddenly switching-on a highly saturated inductance-capacitance circuit, Figure 15 when switching near the zero angle of voltage, and Figure 16 near 45 degrees and 90 degrees. Here, after a short relatively tranquil transient performance, the state changes to a new violent performance for all the parameters measured, as flux, capacitor voltage, inductive voltage, and current. The resistance of this experimental circuit was much higher than that underlying Figure 14 and therefore, the transient time was much shorter. Nevertheless, the main features of the theoreti-

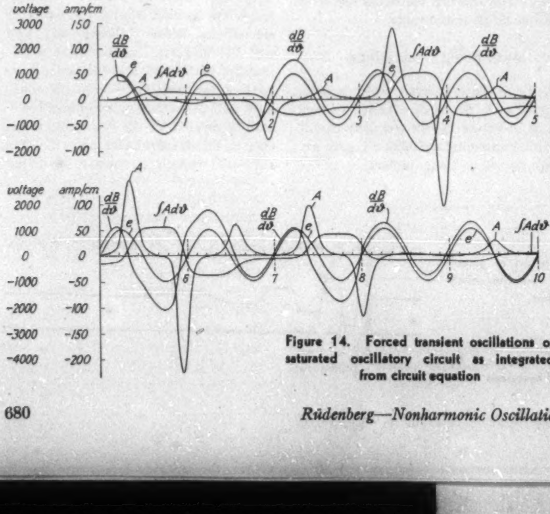

Figure 14. Forced transient oscillations of saturated oscillatory circuit as integrated from circuit equation

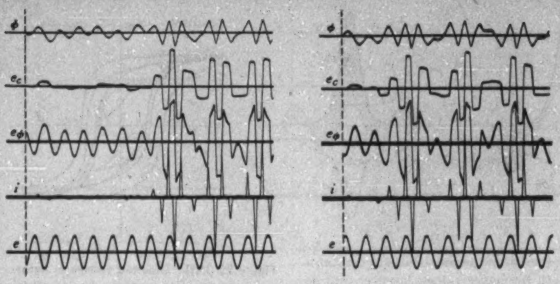

Figure 16. Oscillogram of voltages, current, and flux after switching-on a saturated oscillatory circuit

(left) near 45 degrees (right) near 90 degree phase angle of impressed sinusoidal voltage

cal curve shapes of Figure 14 also are visible in the beginning of Figures 15 and 16.

Steady State and Higher Harmonics

The oscillograms in Figures 15 and 16 indicate that even after the decay of the initial transient fluctuations there remain curve shapes of e and i which are markedly different from the sinusoidal shapes occurring in the steady state of nonsaturated circuits. Experiments show that the shapes are varying, depending on the degree of saturation and hysteresis, on the resistance of the circuit, and on the phase of switching. We know that for the amplitudes of the forced fundamental oscillations, the existence of two stable and one labile states is possible. Although rigorously no superposition can be expected, a consideration of the curve shape and the production of higher harmonics shall be developed here.

For this purpose, we linearize the problem by resolving the actual magnetic characteristic, as in Figure 17, into a proportional component βA and the remainder ΔB. Herein, β is a constant numerical factor designating a virtual permeability somewhere between 1 and μ, so that βA gives a linear rise of the induction and ΔB expresses essentially the nonlinear part of the variation of B. Thus, we set

$$B = \beta A + \Delta B(A) \qquad (29)$$

The latter magnitude is shaded in Figure 17 and changes from positive to negative values within the range of current considered. Substituting this expression into equation 27 and taking the nonlinear component to the right-hand side, we obtain

$$\beta \frac{dA}{d\vartheta} + \rho A + \int A\, d\vartheta = \epsilon(\vartheta) - \frac{d(\Delta B)}{d\vartheta} \qquad (30)$$

In this formulation, the left-hand side is linear and will follow the ordinary rules of proportionality and superposition. On the right-hand side an additional term is acting which can be conceived of as an impressed voltage. We see from Figure 17 that this voltage will change sign several times within every half cycle.

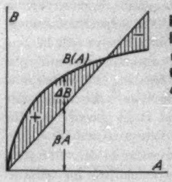

Figure 17. Resolution of curved magnetic characteristic into linear and nonlinear component

Equation 30 may be applied for deriving directly the curve shapes of the steady state oscillations. These were already found by use of the rigorous equation 27, however, they appear in purity only after the passing of the entire transient period which is very long at small resistance. In solving equation 30 we use the method of iteration. As a first step we omit the nonlinear perturbation function ΔB on the right-hand side and obtain in approximation by the conventional way a solution A' from the remaining linear differential equation 30 under the effect of $\epsilon(\vartheta)$. With A' we enter the true characteristic of Figure 17 and obtain a first $\Delta' B$ as function of time. Subtracting the derivative of this curve from the impressed voltage $\epsilon(\vartheta)$ on the right-hand side of equation 30 we solve again the linear equation for A. Either directly or by superposition we obtain an improved solution A''. With this, again, we enter the true characteristic, obtaining an improved $\Delta'' B(\vartheta)$. This procedure may be repeated until no further improvement in the stationary solution occurs. It is obvious that an originally harmonic curve shape of A' will be greatly distorted by this process of repeated introduction of the effect of curvature of the characteristic.

Since the position of the straight line βA in the characteristic diagram is arbitrary, both the left- and right-hand sides of equation 30 depend on the value of β. By suitable choice of β the evaluation may be greatly facilitated. Nevertheless the process is laborious and therefore, we will discuss the development of higher harmonics proper which produce the distortion of the curve shape. If the complete solution of A were present, as in Figure 14, we could directly resolve the total B, and thus $dB/d\vartheta$, into the two components of equations 29 and 30. The true ΔB of Figure 17 would appear as depending on time, as shown in Figure 18 together with the linearly behaving part βA. The two right-hand terms of equation 30 are acting independently and we see that a sinusoidal $\epsilon(\vartheta)$ will bring about a sinusoidal current of supply frequency while ΔB

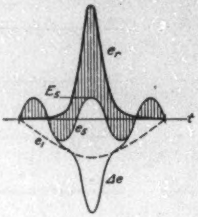

Figure 22 (left). Distorted voltage e_r necessary to compensate resistance drop of natural oscillations and its 5th harmonic e_5 leaving a remainder Δe

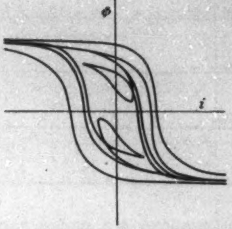

Figure 24 (above). Cathode-ray oscillogram of magnetic characteristic during forced oscillations indicating subharmonic of mode 1/5

will produce the sum of all the superposed higher harmonic currents. By this process we have quantitatively filtered out the cause of the nonsinusoidal behavior.

The nonharmonic voltage

$$\Delta e = \frac{d(\Delta B)}{d\vartheta} \tag{31}$$

contains an extensive series of individual harmonics comprising all the odd modes, and also the even modes if any unsymmetrical condition should be present. The current-amplitude a_ν of an individual higher frequency ν, produced under the effect of a certain sinusoidal amplitude b_ν of the perturbation function ΔB, can be determined from the linear left-hand side of equation 30, yielding

$$j\nu\tau\beta a_\nu + \rho a_\nu - \frac{j}{\nu\tau} a_\nu = -j\nu\tau b_\nu \tag{32}$$

Herein, τ appears as a factor to ν since the latter value refers to the absolute time t rather than to the numerical time ϑ, see equation 26. Thus, the amplitude of the harmonic current is

$$a_\nu = \frac{(\nu\tau)^2}{\sqrt{[\beta(\nu\tau)^2 - 1]^2 + (\rho\nu\tau)^2}} b_\nu \tag{33}$$

At the frequency

$$\nu = \frac{1}{\sqrt{\beta\tau^2}} = \frac{1}{\sqrt{\beta\Lambda C}} \tag{34}$$

which is determined by the self-inductance $\beta\Lambda$, the harmonic current has a resonance maximum of the magnitude

$$a_{\nu r} = \frac{\nu\tau}{\rho} b_\nu = \frac{\nu\Lambda}{R} b_\nu = \frac{\sqrt{\beta\Lambda/C}}{R} \cdot \frac{b_\nu}{\beta} \tag{35}$$

The resonance frequency depends on C and Λ, the resonance current on C, R, and Λ, these three parameters being constants. Both resonance values, however, will depend on β which is given by the position of the linear component of the characteristic in Figure 17. Since this position, and thus the value of β was arbitrarily chosen, such resonances are virtual and may appear for a number of higher harmonic frequencies ν, increasing the amplitudes of all of their currents.

These conclusions would be exact if the values of ΔB in Figure 17 would remain the same over a number of oscillations. However, as the rigorous Figure 14 indicates this is not necessarily so. Therefore, the variations in ΔB, and in βA, will often prevent the resonances from coming into prominence. Nevertheless our considerations show that by marked saturation of the magnetic characteristic in oscillatory circuits a substantial amount of higher harmonics always will be produced which may extend to high multiples of the supply frequency. This refers to the transient as well as to the steady state performance and is in accord with the oscillograms of Figures 15 and 16.

The same results can be derived from a corresponding formulation for parallel connection of a saturated inductance and a constant capacitance. However, the impressed nonharmonic forces now result from the deviation of the magnetizing current from a linear behavior. In either case, series or parallel connection, it is possible to extract one or more of the harmonics, as existing in the irregular curve shapes of current and voltage, by tuned external circuits containing constant inductance and capacitance and thus having a definite resonating frequency.

Subharmonic Resonance

The differential equation 27 and its rigorous solutions as described before implicitly contain the occurrence of all possible kinds of deviations from the simple harmonic behavior, caused by frequencies higher as well as lower than that of the impressed voltage. Since subharmonics occasionally are observed, in the laboratory and in the field, it is suitable to analyze the problem further in order to arrive at a plausible understanding of the physical causes of this complex phenomenon.

Let us consider the conditions for perfect resonance formation between an impressed voltage and the nonharmonic natural oscillations of the saturated circuit as derived before, for example in Figure 4. The inductive and capacitive
